Sleep-disordered breathing (SDB) is defined as “abnormalities of respiratory pattern or adequacy of ventilation during sleep, which includes snoring, mouth breathing, and pauses in breathing”. Sleep-disordered breathing encompasses a wide spectrum of disorders, from snoring to OSAS.

The American Academy of Pediatrics (AAP) and the American Academy of Otolaryngology (AAO) guidelines concur that if a child has symptoms of SDB with significant OSAS on polysomnography (PSG) and adenotonsillar hypertrophy, they should undergo T/A as long as there are no contraindications. However, no evidence specifies the degree of abnormality noted on PSG required for T/A to be indicated. Most reference works define an abnormal PSG to be an apnea-hypopnea index (AHI) greater than 1 or a pulse oximetry below 92%. In practice, an AHI of 5 defines OSAS severe enough for surgery for most otolaryngologists. However, a T/A may be indicated for a symptomatic child with a lower AHI, because specific parameters have not yet been defined by current evidence. More confusing, there are children who have symptoms of SDB but do not have PSG-documented sleep apnea who benefit from T/A. It seems that PSG results do not always correlate with clinical symptoms either pre- or postoperatively. Although PSG is the gold standard for assessment of OSAS, it is an imperfect gold standard.

Finally, although tonsillar size is not always correlated with PSG results, enlargement is considered a requirement for T/A by both the AAP and AAO.

Significant hypertrophy is diagnosed when the tonsils fill more than 50% of the transverse tonsillar space. When a child presents with an abnormal PSG but has no hypertrophy on the visual examination of the pharynx, lateral neck films may provide additional information regarding tonsillar obstruction below the oropharynx or adenoidal obstruction in the nasopharynx.

### Polysomnography

Polysomnography is the gold standard for assessing children who may have OSAS. The AAP guidelines on OSAS recommend that all children and adolescents be screened for snoring. If snoring is present, then further analysis via directed history and physical examination should take place (see Box 339-1).

#### BOX 339-1 Indications for Polysomnography

##### AMERICAN ACADEMY OF PEDIATRICS GUIDELINES

###### *Snoring history plus any of the following:*

- History is positive for:
  - SDB
  - Frequent snoring (>3 nights/week)
  - Labored breathing during sleep
  - Gasps/snorting noises/observed episodes of apnea during sleep
  - Sleep enuresis
  - Sleeping in a sitting position or with the neck hyperextended
  - Cyanosis
  - Headaches on awakening
  - Daytime sleepiness
  - ADHD symptoms
  - Learning problems
- Physical examination reveals:
  - Tonsillar hypertrophy
  - Under or overweight
  - Adenoidal facies
  - Micrognathia/retrognathia
  - High arched palate
  - Failure to thrive
  - Hypertension

##### AMERICAN ACADEMY OF OTOLARYNGOLOGY GUIDELINES

- Obesity
- Down syndrome
- Craniofacial abnormalities
- Neuromuscular disorders
- Sickle cell disease or mucopolysaccharidoses
- Uncertainty between physical findings and history

SDB, symptoms of sleep disordered breathing.

Note: this guideline is not intended to restrict PSG only to these indications, but rather to define where PSG should be performed before a T/A.

Approximately 10% of children have nighttime snoring, but only one-third of these have OSAS found on PSG. Therefore, infrequent snoring alone is not a criterion for referral for PSG testing. At least one finding in addition to frequent snoring (defined as being present >3 nights/week) is needed and may include a history of labored breathing during sleep, gasping/snorting noises, observed apnea, nocturnal enuresis, sleeping in a sitting position or with the neck hyperextended, cyanosis, headaches on awakening, daytime sleepiness, attention deficit/hyperactivity disorder symptoms, or learning problems. Other findings on physical examination might include: tonsillar hypertrophy, under- or overweight, adenoidal facies, micrognathia, retrognathia, high arched palate, failure to thrive, or hypertension. If frequent snoring plus one of these other criteria are found, then PSG should be performed. Another option is to refer the patient to a sleep specialist or otolaryngologist for a more extensive evaluation. Also per the AAP guidelines, if PSG is not available, then alternative diagnostic tests such as video recording, nocturnal oximetry, daytime nap PSG, or ambulatory PSG may be ordered.

The American Academy of Sleep Medicine, similar to the AAP, recommends PSG any time there is a concern about symptoms that could indicate OSAS.

In contrast with the AAP, the AAO has more selective recommendations pertaining to PSG before T/A (see Box 339-1). The AAO recommends PSG for children suspected of OSAS who are obese or who have Down syndrome, craniofacial abnormalities, neuromuscular disorders, sickle cell disease, or mucopolysaccharidoses. The AAO guideline, which was written as a quality improvement document for head and neck surgeons, also recommends PSG when there is uncertainty between physical findings and the history. The AAO guideline states that there is not enough evidence to recommend portable monitoring devices. Furthermore, the AAO does not recommend PSG for all children who are being considered for T/A, but rather for those with the clinical presentations listed above.

In clinical practice, fewer than 10% of children and adolescents who undergo T/A undergo preoperative PSG. Thus, children who have none of the risk factors listed in the AAO guidelines but who have significant symptoms of SDB and tonsillar hypertrophy will likely undergo T/A without PSG if referred to an otolaryngologist directly. The AAP guidelines support a direct referral in this situation.

Polysomnography is also used to help identify children with more severe OSAS who need to be monitored in an inpatient setting after T/A, because most T/A surgeries are performed as outpatient procedures (see Inpatient versus Outpatient Setting).

Children who have severe OSAS on preoperative PSG may need repeat postoperative PSG if symptoms remain to determine the need for further management with continuous positive airway pressure (CPAP) or other modalities.

In summary, although PSG seems to be a useful clinical tool in evaluating the child or adolescent with SDB as noted above, opinions differ as to when PSG is necessary.

### Medical Options

The AAP supports the option to prescribe topical intranasal corticosteroids when OSAS is mild or when T/A is contraindicated. Also, recent evidence demonstrates a benefit from montelukast for nonobese children with mild OSAS (AHI <10). In this study, the AHI decreased by greater than 50% in 65.2% of children after medication was used for 12 weeks.

### Prognosis

Polysomnography and parental questionnaires assessing sleep disturbance, growth, breathing problems, emotional problems, hyperactivity, school problems, enuresis, aggression, swallowing disorders, speech problems, parental anxiety, activity limitations, and somatization behaviors show significant resolution of these symptoms after T/A. Also, there are reports of significant improvements in quality of life. Nonobese children with SDB who undergo T/A can expect a resolution of symptoms 70% to 80% of the time. However, in a meta-analysis of obese patients, a resolution of SDB occurred in only 10% to 25% of patients. Thus, obese children and those with neuromuscular weakness, craniofacial anomalies, severe preoperative OSAS, family history of sleep apnea, and African American ethnicity are less likely to have a complete resolution of sleep abnormalities after T/A and may warrant PSG postoperatively.

The Childhood Adenotonsillectomy Trial investigators published a recent, well-designed, randomized controlled study that demonstrated no difference in executive function or attention for those undergoing T/A as measured by the Developmental Neuropsychological Assessment test administered 6 to 7 months postoperatively. However, there was improvement in the T/A group in the Connors' rating scales (both teacher and parent), the Epworth Sleepiness Scale, and 2 quality-of-life measures. On PSG, there was significantly greater improvement in AHI score, oxygen desaturation index, hypercapnia and arousal index in the T/A group. Finally, reversal of obstructive sleep apnea was more common in the T/A group (79% vs 46%;  $p < 0.001$ ). Of note in this study, obese children improved in many of the parameters with T/A. Thus, despite finding no difference in attention and executive function, there were many improvements in other parameters for those undergoing T/A for OSAS symptoms.

Treatment with CPAP is indicated for children who do not respond to T/A. Also, weight loss, montelukast, and perhaps nasal steroids may be important adjunctive treatments.

### Recurrent Tonsillitis

Many children with recurrent tonsillitis are referred for T/A. The criteria for recommending this surgery have been a subject of significant controversy in the medical literature. The AAO Guideline on Tonsillectomy in Children recommends watchful waiting for children who do not meet the stringent Pittsburgh criteria (Box 339-2). Physicians may refer children for T/A if these criteria are met.

### BOX 339-2 Tonsillectomy and Adenoidectomy for Recurrent Tonsillitis (Pittsburgh Criteria)

#### DOCUMENTATION REQUIRED:

1. Frequency criteria:
  - 7 episodes in the past year
  - 5 episodes per year for the past 2 years
  - 3 episodes per year for the past 3 years
2. Sore throat plus 1 of the following clinical features:
  - Temperature  $>101^{\circ}\text{F}$  ( $38.3^{\circ}\text{C}$ ) OR
  - Cervical lymphadenopathy ( $>2$  cm) OR
  - Tonsillar exudate OR
  - Positive test for Group A  $\beta$ -hemolytic streptococci
3. PLUS antibiotics for proven or possible streptococcal infection

If not documented, physician should observe patient closely to determine if above clinical pattern is continuing prospectively.

Baugh RF, Archer SM, Mitchell RB, et al.; American Academy of Otolaryngology—Head and Neck Surgery Foundation. Clinical practice guideline: tonsillectomy in children. *Otolaryngol Head Neck Surg.* 2011; 144(1 Suppl):S1–S30; and Paradise JL, Bluestone CD, Bachman RZ, et al. Efficacy of tonsillectomy for recurrent throat infection in severely affected children. Results of parallel randomized and nonrandomized clinical trials. *N Engl J Med.* 1984;310(11):674–683.

The Pittsburgh criteria are derived from a study by Paradise on children severely affected by recurrent pharyngitis. The criteria include at least 7 episodes in 1 year, 5 episodes in 2 successive years, or 3 episodes per year in 3 years. Each episode should have documentation of sore throat plus one or more of the following 4 criteria: temperature greater than  $101^{\circ}\text{F}$  ( $38.3^{\circ}\text{C}$ ), cervical lymphadenopathy, tonsillar exudate, or positive culture for group A  $\beta$ -hemolytic streptococci. Additionally, the criteria include the child having been prescribed antibiotics in a conventional dosage for proved or suspected streptococcal episodes (see Box 339-2).

The children in the Paradise study who met these criteria and who underwent T/A had consistently lower throat infection rates than the observation group, especially in relation to episodes rated moderate or severe. After 1 year, the surgical group had a 14-fold reduction in throat infection episodes rated as moderate or severe; after 2 years, a 6-fold reduction occurred. In addition, sore throat days and sore throat-associated school absences were reported more often for individuals who were treated nonsurgically. Despite the better outcomes in the surgical group, rates of having more than 1 moderate or severe infection in the control group in the subsequent follow-up years were relatively low (year 1: 26%; year 2: 24%; and year 3: 5%). Therefore, the conclusion might be made that this low rate of infection in subsequent years favors observation over surgical intervention. A 14% complication rate occurred in the

surgical group, all of which were judged to be self-limited and readily managed.

Additional research by Paradise and Bluestone analyzed the issue of T/A for children with less severe criteria than those reported from their original study. Using a randomized controlled trial, they found statistically significant, but not clinically significant, differences between the surgical group and controls and reported that moderate inclusion criteria did not justify the risks of surgery, including morbidity (7.9% complication rates) and cost. Van Staaïj and colleagues, who proposed a wait-and-see approach for persons who do not meet the stringent Pittsburgh criteria, supported this concept. In this study, a 4% complication rate was noted, with 1% requiring repeat surgery for hemorrhage and 2.6% having severe nausea or dehydration, which were thought to outweigh the minimal reductions in the frequency of tonsillitis. Because of the cost and complications associated with surgery, most experts recommend presenting surgery as an option (not recommendation) only for children with recurrent pharyngitis who meet the stringent Pittsburgh criteria.

More recent studies, including a Cochrane systematic review, revealed minimal benefit during the first postoperative year of 1.4 fewer sore throat episodes in the surgical group vs. control group that was negated by the one sore throat incurred by those with the surgical procedure.

Two additional systematic reviews both showed just modest improvement in those who had T/A. One study showed 43% fewer sore throat episodes in the first year; the number needed to treat to reduce sore throat by 1 per month was 11. In another review of 13 randomized trials, the T/A group had 1.2 fewer sore throat episodes and 2.8 fewer missed school days per person-year. In each of these studies, the control group also showed significant improvement in tonsillitis episodes.

In developing the most recent AAO guideline that provided a step-by-step logical analysis of the above literature, the panel felt there was not a preponderance of benefit over harm for T/A even for children meeting strict Pittsburgh criteria. Therefore, T/A is stated to be an option that physicians “may recommend” for those meeting the Pittsburgh criteria. Therefore, there is a role for shared decision-making with caregivers. Weighing the risk of complications compared to modest benefits of T/A, watchful waiting remains a reasonable alternative even for children who meet the Pittsburgh criteria.

The AAO guideline for T/A recommends assessing for modifying factors in children with recurrent throat infection who do not meet the Pittsburgh criteria. (see Box 339-3). These conditions include multiple antibiotic allergies making treatment of recurrence difficult and recurrent pharyngitis associated with peritonsillar abscess or PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and adenitis). The presence of these circumstances might lower the threshold for recommending T/A.

### Other Indications

Tonsillectomy is indicated in cases of suspected malignancy where there is asymmetric tonsillar hypertrophy

### BOX 339-3 Modifying Factors for Tonsillectomy in Patients Not Meeting Pittsburgh Criteria

- Multiple antibiotic allergies making treatment of recurrence difficult
- Recurrent pharyngitis associated with peritonsillar abscess
- PFAPA (periodic fever, aphthous stomatitis, pharyngitis, and adenitis)

Derived from Baugh RF, Archer SM, Mitchell RB, et al.; American Academy of Otolaryngology—Head and Neck Surgery Foundation. Clinical practice guideline: tonsillectomy in children. *Otolaryngol Head Neck Surg.* 2011; 144(1 Suppl):S1–S30.

in the setting of lymphadenopathy larger than 3 cm, splenomegaly, fever, or sweats.

Other reported indications that lack evidence include T/A to treat pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections, chronic tonsillitis, muffled speech, halitosis, malocclusion, or group A  $\beta$ -hemolytic carrier state. The theoretical benefits of surgery for these conditions, for which there is scant evidence, do not justify the risk of T/A.

Adenoidectomy without tonsillectomy has not been studied as well as T/A. Indications may include chronic otitis media with effusion if pressure-equalization tubes have to be reinserted. This is especially the case in children older than 4 years of age, in whom adenoidectomy seems to be effective in decreasing the rate of pressure-equalization tube reinsertion. Other indications include significant nasal obstruction, recurrent sinusitis, and chronic adenoiditis.

### Contraindications

Relative contraindications for T/A include uncontrolled bleeding disorders and medical conditions causing the child to be unstable for anesthesia. Special consideration should be given for children with submucosal cleft palate who are at risk for velopharyngeal insufficiency after T/A. Physicians should evaluate for the presence of a bifid uvula or a notched hard palate as clues to making this diagnosis preoperatively.

## PERIOPERATIVE MEDICATION

### Steroids

The AAO guideline strongly recommend one intraoperative dose of intravenous dexamethasone to children undergoing T/A (dose 0.0625–1 mg/kg—total dose range 8–25 mg). This was demonstrated in a Cochrane review to reduce postoperative nausea and vomiting (relative risk 0.54; 0.42–0.69) with 4 being the number needed to treat. Also, steroid treatment resulted in less postoperative throat pain and earlier return of oral intake. There were no significant negative consequences of steroid use. This Cochrane review also showed that postoperative hemorrhages were not increased with steroid use.

## Antibiotics

The AAO guideline make a strong recommendation against the use of antibiotics in the perioperative period. This recommendation was based on a Cochrane review of studies that showed no significant benefit.

## Analgesia

The adequate management of pain is important in children who underwent T/A. Generally, pain lasts a week or more and can lead to poor oral intake and dehydration. The AAO recommends ensuring adequate hydration as an important measure after T/A in addition to medications to reduce pain. There was no superiority of around-the-clock over as-needed medication administration except in one study that used hydrocodone.

Concerns about the safety of opioids have caused many surgeons to avoid their use in children younger than 6 years or those with other risk factors for OSAS. Recommended pain management for these children includes acetaminophen (total daily dose of 15 mg/kg/dose up to 5 times per day, maximum dose 4,000 mg/day); ibuprofen (5–10 mg/kg/dose up to 4 times per day, maximum dose of 40 mg/kg/day); and oral corticosteroids in a single dose postoperatively. Of note, no increase in postoperative bleeding was noted with nonsteroidal anti-inflammatory drugs except in the case of ketorolac, where post-T/A hemorrhage rates of 4.4% to 18% have been reported.

The use of narcotics, especially codeine, has received increased scrutiny with recent reports of deaths after T/A in children given codeine. This prompted a US Food and Drug Administration Drug Safety Communication stating that codeine should not be used for pain following T/A. When codeine is ingested, it is converted to morphine in the liver by cytochrome CYP-2D6. Certain children are ultrarapid metabolizers, which can lead to higher than expected levels of morphine and result in respiratory depression. Best practice is to avoid codeine analgesia.

Noncodeine opiates such as oxycodone are still being used in clinical practice in children who undergo T/A. It is unresolved how safe this practice is, because children with significant OSAS were excluded from studies of analgesia after T/A. One study demonstrated that those with OSAS and a preoperative oxygen saturation nadir below 85% had heightened sensitivity to opioid therapy. Recently, a survey of anesthesiologists conducted by the Society for Pediatric Anesthesia examining deaths or serious adverse events after T/A found significantly higher rates of death from apnea among those at risk for OSAS based on risk factors/symptoms. Many of these children received opiate analgesia post-operatively. Most children undergoing T/A do not have a preoperative PSG, and therefore the physician may not know the degree of OSAS in the child. Based on their review of the literature and the survey results, the authors conclude that opiates are responsible for deaths after T/A, with special concern in high-risk children. A normal dose may be too high for the OSAS patient. Therefore, the authors recommended a 50% reduction in opiate dosing for those in the higher risk categories for postoperative apnea.

Oxycodone is an example of a noncodeine opioid that may be considered for pain after T/A. Oxycodone has a more favorable clinical profile than codeine, fewer side effects, more effective analgesia, and less concern with CYP-2D6 metabolism. While oxycodone provides analgesia without metabolism, a small amount of the drug is metabolized via the CYP-2D6 pathway into noroxycodone and oxymorphone. Noroxycodone has weaker analgesic activity compared to oxycodone; oxymorphone is active, but only a small amount (<15%) of the parent drug is converted to this metabolite. Oxycodone is a Schedule II drug. This should be taken into consideration for prescribing, as the prescription must be provided to the pharmacy on paper and cannot be phoned in for dispensing. One advantage of this product is the availability of a tablet and liquid formulation. The liquid can be used to measure small doses for children that do not need a whole tablet for their dose or cannot swallow a tablet.

Hydrocodone, also an opioid agonist, is metabolized by CYP-2D6 into hydromorphone and norhydrocodone. Hydromorphone is a major active metabolite from the CYP-2D6 pathway that can have anywhere from a 33- to 100-fold increase in binding affinity for  $\mu$ -opioid receptors over hydrocodone. Norhydrocodone is metabolized primarily by the CYP-3A4 pathway, and has lesser activity. Hydrocodone is a Schedule III drug. Prescriptions can be written or called in to a pharmacy for dispensing. It is unavailable as a liquid by itself, however, does have a liquid preparation in combination with acetaminophen. When the combination product is prescribed, parents must be counseled not to give regular acetaminophen along with the combination product.

In summary, more research is needed to determine the risk involved in the use of noncodeine opiates, especially in those cases where the degree of OSA was not determined preoperatively. Current practice is to use noncodeine opiates when acetaminophen or ibuprofen are not controlling pain. The dosage should be reduced for those at risk for apnea. (see Box 339-4) Finally, parents should be instructed to be sure to dose medications accurately, especially by using a syringe for liquid medications. Also, excessive acetaminophen dosage should be avoided when using hydrocodone/acetaminophen combinations.

## PROCEDURES

Over the years, various techniques have been used to remove tonsils and adenoids. Techniques have evolved more recently with the goal of decreasing intraoperative blood loss, minimizing postoperative pain, and decreasing postoperative complications.

Cold dissection with a scalpel, surgical scissors, guillotine, or snare has been the traditional method of removing the tonsil by separating the capsule from the superior pharyngeal constrictor muscle and gaining hemostasis with suture ligation. The adenoids have traditionally been removed with curettage. Electrocautery was later added as a tool to achieve hemostasis in the nasopharynx and tonsillar fossa. Although still deemed a safe technique, it can be associated with considerable blood loss.

**BOX 339-4 Usual Doses for Analgesia**

- Acetaminophen
  - 15 mg/kg/dose (maximum dose of 75 mg/kg/day, in  $\leq 5$  divided doses/day with 4,000 mg/day)
- Ibuprofen
  - 5–10 mg/kg/dose up to 4 times/day (maximum dose of 40 mg/kg/day); administer with food if GI upset occurs
- Opioids
  - Note: for opioid analgesia, consider reducing dose by 33% to 50% for patients at risk for or documented to have OSAS.
  - Oxycodone
    - Patient weight  $< 50$  kg, over 6 months old: Oral: Initial dose: 0.1–0.2 mg/kg/dose every 4–6 hours as needed; for severe pain, some experts have recommended an initial dose of 0.2 mg/kg/dose; usual maximum dose range: 5–10 mg
    - Patient weight  $\geq 50$  kg: Oral: Initial dose: 5–10 mg every 4–6 hours as needed; for severe pain, an initial dose of 10 mg may be used; usual maximum dose: 20 mg/dose
  - Hydrocodone and acetaminophen (Norco):
    - Patient weight  $< 50$  kg: Oral: Usual initial dose: hydrocodone 0.1–0.2 mg/kg/dose every 4–6 hours
    - Patient weight  $\geq 50$  kg: Oral: Usual initial dose: hydrocodone 5–10 mg every 4–6 hours
    - Note: opioid-naïve patients—limited data available in infants and children  $< 2$  years; use caution. Also, the maximum daily dose of acetaminophen should be limited to  $\leq 75$  mg/kg/day in  $\leq 5$  divided doses; should not exceed 4,000 mg/day

GI, gastrointestinal; OSAS, obstructive sleep apnea syndrome.

Monopolar electrocautery was then introduced as a technique to vaporize adenoid tissue and dissect the tonsils from the fossae. Monopolar electrocautery is currently the most popular technique because it can be performed rapidly with little or no blood loss with equipment that is relatively inexpensive and widely available (Figure 339-1 and Figure 339-2). Electric energy generating temperatures of 400°C to 600°C has the ability to coagulate blood vessels and achieve hemostasis during the dissection. Electrocautery reduces the intraoperative blood loss and the risk of immediate postoperative hemorrhage, but may increase the risk of secondary hemorrhage and postoperative pain when compared with cold dissection, because of the thermal injury to the underlying constrictor muscle. Although rare, airway fire and other fire-related injuries are potential risks of using electrocautery in an oxygen-rich environment.

Surgical lasers have been used in T/A for the last few decades. The oropharynx is easily accessible with laser handpieces used in either illumination (thermo-coagulation) or contact (vaporization) modes. The potential advantages to using lasers include less superior pharyngeal constrictor muscle injury and less

**Figure 339-1** Operative field prepared for electrocautery tonsillectomy.

**Figure 339-2** Tonsil completely removed from the pharyngeal constrictor. (Courtesy of Louis Petcu MD MS.)

pain when compared with the more popular electrocautery technique. In certain cases, electrocautery may be required as an adjunct to achieve hemostasis. Special equipment and precautions must be used by the operating room staff to avoid injury by reflected or misdirected laser light and to avoid airway fire.

Other techniques evolved more recently that allow tonsil removal with less potential for thermal injury to the surrounding tissue. One of these includes the harmonic scalpel, which uses ultrasonic energy to cut and coagulate at a temperature less than 100°C. Another technique includes the coblation device, which uses bipolar radiofrequency energy to ablate and coagulate soft tissue by generating a high-energy plasma field. The ionized plasma field is generated by radiofrequency current that passes through a normal saline medium, working at a much lower temperature of

40°C to 70°C. The Peak plasma blade (Medtronic) uses short bursts of radiofrequency via a highly insulated cutting electrode. The pulsed waveforms deliver less energy, allowing this instrument to work with a temperature range of 40°C to 170°C. A disadvantage of the newer technology is the cost of the disposable hand-pieces that are used with each of these units.

Extracapsular T/A involves the traditional method of removing the tonsils by separating the tonsillar capsule from the surrounding muscles. An alternative method includes using instruments to remove 90% to 95% of the tonsil medial to the tonsillar capsule. This technique intentionally leaves the tonsillar capsule to cover the superior constrictor muscle as a physiologic bandage to minimize swallowing difficulty postoperatively. The procedure may be performed with any of the powered instrumentation as described above or with a microdebrider. This intracapsular technique may be used as an alternative for management of younger patients with obstructed breathing, but may not be appropriate for patients with recurrent infections.

## INPATIENT VS OUTPATIENT SETTING

The decision of whether to perform T/A in the inpatient or outpatient setting hinges on the presence of risk factors as noted in the AAP, AAO, and American Society of Anesthesiologists (ASA) guidelines. Note that there is not a consensus as to what PSG indications require inpatient monitoring. (see Box 339-5).

The AAO guideline cites the ASA guideline, which defines severe OSA as an AHI score greater than 10. The ASA uses a scoring system that includes a combination of severity of OSAS, invasiveness of surgery, and requirement for opioids to determine the need for inpatient monitoring. Of note, using this scoring tool, lower AHI scores may warrant inpatient admission. The AAP uses an AHI score of 24 or higher for inpatient monitoring or where the lowest oxygen saturation is less than 80% or partial pressure of carbon dioxide ( $P_{CO_2}$ ) of 60 or higher on preoperative PSG. These children may also warrant more caution when using narcotic pain medications postoperatively. There are additional criteria recommended by the AAP, the AAO, and the ASA when deciding whether to admit to an inpatient setting postoperatively (see Analgesia).

## COMPLICATIONS

Life-threatening complications in T/A and adenoidectomy are rare and generally involve catastrophic hemorrhagic and respiratory complications. Mortality rates after T/A are difficult to estimate because death is a very rare outcome of this procedure. Most of the studies date back to the 1960s and 1970s. The estimated mortality rate in England was 1:10,000 (1945 to 1965), 1:10,000 (1957 to 1961), 1:16,000 (1961 to 1969), and 1:35,000 (1970s). More recent studies estimate ranges from 1:33,921 (2003–2004), 1:27,000 to 1:100,000.

This improvement in mortality can likely be attributed to improved anesthesia, monitoring equipment, medications, and preparation for hemorrhagic consequences. As anesthetic and surgical techniques and medications continue to evolve and improve, this mortality rate will likely be further reduced.

### BOX 339-5 Potential Indications for Inpatient T/A

- <3 years
- Score of  $\geq 5$  on the Scoring System for Perioperative Risk, found in the ASA Practice Guidelines for the Perioperative Management of Patients With Obstructive Sleep Apnea.
- Severe OSAS on polysomnography (AHI  $\geq 24$  in the AAP guidelines vs  $>10$  in the ASA, AAO guidelines; significant hypercapnia (peak  $P_{CO_2} \geq 60$  mm Hg))
- Lowest oxygen saturation  $<80\%$  (either on preoperative polysomnography or during observation in the recovery room postoperatively)
- Cardiac complications of OSAS
- Failure to thrive
- Obesity
- Craniofacial anomalies
- Neuromuscular disorders
- Current or recent respiratory infection
- Significant asthma
- African American race (4-fold increased risk of OSAS)
- Down syndrome
- Mucopolysaccharidosis and other serious metabolic disorders
- Sickle cell disease
- Central apnea

AAO, American Academy of Otolaryngology; AAP, American Academy of Pediatrics; AHI, apnea-hypopnea index; ASA, American Society of Anesthesiologists;  $P_{CO_2}$ , partial pressure of carbon dioxide; OSAS, obstructive sleep apnea syndrome.

Recent reviews of causes of mortality by the AAO T/A guidelines indicate bleeding as cause in one-third of cases, with other causes being aspiration, cardiopulmonary failure, electrolyte imbalance, or anesthetic complications. Another study demonstrated airway compromise as the major cause of death in malpractice claims. One study based on a survey of anesthesiologists found that a larger proportion of deaths were because of apnea among those who were at high risk for obstructive sleep apnea. Those who were at low risk for OSAS had a higher proportion of death from hemorrhage.

A relatively common complication of T/A and adenoidectomy is minor postoperative bleeding, which is thought to occur at a frequency of 1% to 2% of all cases in the United States. Postoperative hemorrhage can be divided into 2 groups. The immediate postoperative hemorrhage occurs within 24 hours of the T/A or adenoidectomy and is generally thought to be related to surgical technique. The second form of post-tonsillectomy bleeding occurs without identifiable cause and is delayed; it occurs approximately 1 to 2 weeks after surgery.

Postoperative airway obstruction occurs mainly in the child younger than 3 years. In most cases, this complication is caused by edema of the palate, tongue, or lateral pharynx. High-risk patients (Box 339-5) should be identified preoperatively and observed closely in the postoperative period.

**Table 339-1** Post-T/A Complications

COMPLICATION	ONSET	PRESENTATION	TREATMENT
Immediate hemorrhage	0–24 hr	Oral bleeding Hemoptysis Hematemesis	Exploration and ligation of blood vessel
Delayed hemorrhage	5–14 days	Oral bleeding Hemoptysis Hematemesis	Ice pack to neck and iced liquids Elevation of head and neck AgNO <sub>3</sub> cautery Blood vessel ligation Coagulopathy work-up
Immediate airway compromise	Extubation—2 hr	Cyanosis Stridor	Rule out upper airway obstruction/aspiration Rule out laryngospasm Rule out pulmonary edema
Delayed airway compromise	2–24 hr	Shortness of breath Stridor	Intravenous or oral steroid Nasopharyngeal airway
Dehydration	1–6 days	Lethargy Tachycardia Anuria/oliguria	Intravenous rehydration Pain control, hydration Parent education

Occasionally, children with severe OSAS will exhibit postoperative, postobstructive pulmonary edema or central apnea. Other rare complications of T/A include Grisel syndrome (atlantoaxial subluxation—more common in Down syndrome), Lemierre syndrome (parapharyngeal infection with internal jugular vein thrombosis), and posttonsillectomy taste distortion.

Table 339-1 provides a summary of common post-T/A complications.

## SUMMARY

The main indications for T/A are children who have:

1. A combination of SDB or obstructive sleep apnea documented on overnight polysomnography, and tonsillar hypertrophy on physical exam (Best option)
2. Recurrent tonsillitis meeting the Pittsburgh criteria (Option) or if criteria are not met, considering modifying factors that would support T/A (Best option) such as multiple antibiotic allergies, recurrent peritonsillar abscess or PFAPA.
3. Suspected malignancy

In the diagnosis of OSAS, the AAP recommends wide usage of PSG for children who snore and have at least one other symptom or physical finding that supports the diagnosis of OSAS. The AAO, however, recommends PSG only for children who have symptoms of SDB if they are high risk or in cases where there is uncertainty of clinical findings as to whether OSAS is present. In practice, the presence of SDB plus significant tonsillar hypertrophy in nonobese, low-risk children may suffice for T/A without requiring PSG.

Regarding the surgery, a single dose of dexamethasone is strongly recommended intraoperatively, antibiotics are not recommended, and pain control is recommended. Special caution about the use of opioid analgesia should be applied to treating postoperative pain, especially for children who are at risk for or found to have OSAS who undergo T/A in outpatient centers. Specifically, codeine should not be used.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

## Chapter 340

# TOXIC SHOCK SYNDROME

Chokechai Rongkavilit, MD

Toxic shock syndrome (TSS) is a disease mainly caused by *Staphylococcus aureus* and *Streptococcus pyogenes*. Staphylococcal TSS can be divided into 2 categories based on the causal association of infection: menstrual and nonmenstrual. Menstrual TSS usually occurs a few days after initiation to a few days after completion of menstruation and is associated with tampon usage in women colonized vaginally by superantigen-producing *S aureus*. A public health campaign on proper tampon use resulted in a shift from menstrual cases to predominantly nonmenstrual cases. Nonmenstrual TSS occurs as a complication of *S aureus* infections after surgical procedures, burns, or influenza pneumonia. Population-based active surveillance for staphylococcal TSS conducted in the Minneapolis-St. Paul area from 2000 to 2006 showed no increase in incidence during that time.

Staphylococcal TSS may occur when a patient who lacks protective antibodies against staphylococcal toxins becomes colonized or infected with toxin-producing *S aureus*. Staphylococcal TSS is likely under-recognized in children because of a common misconception that a foreign body is required for the illness to develop. The overall case fatality rate is from 2% to 5%, which is lower than the reported fatality rates of streptococcal TSS. Mortality is increased significantly—by up to 50%—if adult respiratory distress syndrome or refractory hypotension is apparent. Moreover, nonmenstrual TSS seems to carry a worse prognosis than menstrual TSS, probably because of the delay in diagnosis and the more serious nature of the primary infection.

*Streptococcus pyogenes*, also known as group A  $\beta$ -hemolytic *Streptococcus* (GAS), can cause severe invasive diseases including necrotizing fasciitis, necrotizing myositis, bacteremia, and sepsis; all of which may lead to streptococcal TSS, which is characterized

by vascular collapse, hypotension, and multiorgan failure. Beginning in the 1980s, reports began to shift in the epidemiology of GAS disease toward the occurrence of more severe clinical illness. Subsequent reports indicated the emergence of a toxic shock-like syndrome caused by GAS. Patients with streptococcal TSS have epidemiologic features that distinguish them from patients with other invasive GAS infections, including younger age, alcohol abuse, and fewer underlying illnesses. Published incidence rates of severe invasive GAS infections have ranged from 1.5 to 7.0 cases per 100,000 population annually. Outbreaks of severe invasive GAS infections have occurred in some closed environments, such as military bases, nursing homes, and hospitals. In children, varicella is the most important risk factor associated with invasive GAS infections, including streptococcal TSS. A population-based surveillance study in the United States indicated a high fatality rate associated with invasive GAS infections, with rates of 22% for necrotizing fasciitis and 45% for streptococcal TSS. Although the overall fatality rate of invasive GAS diseases is lower in children (5%–10%) than in adults (30%–80%), the case fatality rate associated with streptococcal TSS remains high in children and adults.

## ETIOLOGY AND PATHOGENESIS

Toxic shock syndrome is a superantigen-mediated disease. Superantigens are potent immunostimulators that are able to simultaneously bind to the major histocompatibility complex class 2 molecules and the T-cell receptor. This binding results in the activation of a large number of T cells that express specific V- $\beta$  subsets of the T-cell repertoire and leads to increased secretion of large quantities of specific cytokines, such as tumor necrosis factor  $\alpha$  and interleukin 1 $\beta$  and T-cell mediators such as interleukin 2 and interferon  $\gamma$ . Unrestrained release of these cytokines may activate the complement, coagulation, and fibrinolytic cascades, resulting in the hypotension, tissue injury, and multiorgan failure characteristic of TSS. A specific staphylococcal exotoxin (SE) known as TSS toxin type 1 (TSST-1) and SEs A, B, C, D, E, and H are a family of superantigens associated with staphylococcal TSS. TSST-1 is responsible for 75% of cases, and SEs are responsible for the remainder. TSST-1 is found in over 90% of menstrual staphylococcal TSS cases and approximately 50% of nonmenstrual cases. Various SEs are found in the other 50% of nonmenstrual cases. Approximately 20% of all clinical isolates of *S aureus* produce TSST-1, which is regulated by a gene known as *agr*. All strains of *S aureus* possessing the *agr* gene produce TSST-1, but the amount of toxin produced varies by strain. Physical and chemical factors are known to influence the production of TSST-1. These factors include pH (toxin production increases between pH 6 and 8), oxygen concentration (toxin production increases at lower oxygen levels), concentration of carbon dioxide (toxin production increases with rising carbon dioxide levels), and concentration of divalent cations (especially magnesium). The absence of antibodies to TSST-1 is a major risk factor for the development of staphylococcal TSS, and it explains why not all patients exposed to virulent

*S aureus* strains develop TSS. The prevalence of antibodies against TSST-1 is over 90% in adults, but is lower in children. A failure to generate anti-TSST-1 antibodies after an episode of TSS predisposes a person to recurrent TSS episodes. Similar to TSST-1, SEs also are potent mediators of cytokine production and release; they behave in a manner similar to TSST-1 in producing clinically comparable TSS disease.

The pathogenic mechanisms responsible for invasive GAS infections have yet to be completely defined. Skin and mucous membranes, often at the site of minimal or inapparent local trauma, are common portals of entry of GAS. The opened lesion of chickenpox has been identified as a risk factor for acquiring invasive GAS diseases, including streptococcal TSS, in otherwise healthy children. Severe invasive GAS infections, however, rarely occur after an episode of acute GAS pharyngitis. The major human host defense against invasive GAS infection is that of phagocytosis and killing by polymorphonuclear leukocytes. Thus, a critical somatic GAS virulence factor is an antiphagocytic surface constituent known as M protein. M protein forms an elongated structure on the bacterial surface and exerts its antiphagocytic effect by interfering with opsonization via the alternate complement pathway. In addition, M protein is shed from the bacterial surface and forms a complex with fibrinogen. The M protein–fibrinogen complexes bind to integrins on the surface of polymorphonuclear leukocytes, activating these cells to adhere to endothelium and degranulate, releasing a wide variety of hydrolytic enzymes and producing a respiratory burst. The resulting damage to the underlying endothelium leads to vascular leakage and hypercoagulability, which in turn cause the hypotension, disseminated intravascular coagulation, and organ damage that are characteristic of TSS. Strains of GAS isolated from patients with TSS are not of a single M type, but M1 and M3 infections have been commonly associated with invasive diseases and streptococcal TSS.

Most cases of streptococcal TSS are caused by GAS strains that produce bacterial superantigens known as the streptococcal pyrogenic exotoxins (Spe). Their structures are similar to each other and to the structures of staphylococcal superantigens. The probable direct importance of streptococcal pyrogenic exotoxins, particularly exotoxin A (SpeA), in the development of streptococcal TSS is emphasized by the total inability of patients' sera to neutralize the lymphocyte mitogenic properties of SpeA, the known biologic property of SpeA as a superantigen. Among the streptococcal pyrogenic exotoxins, SpeA is the most potent inducer of massive T-cell proliferation and interferon  $\gamma$  and tumor necrosis factor  $\beta$  production. In addition, there is evidence that the host immunogenetics, specifically human leukocyte antigen class II allelic variation, contribute to differences in the severity of invasive GAS infections, including streptococcal TSS, through the ability to regulate immunomodulator responses triggered by streptococcal superantigens. Patients with severe GAS disease have significantly lower serum levels of protective antibodies against M protein and superantigens compared with serum samples from noninvasive cases. These findings provide evidence

that a lack of protective humoral immunity against GAS virulence factors contributes to susceptibility to invasive infection.

## EVALUATION

### Clinical Presentation

#### *Staphylococcal Toxic Shock Syndrome*

Staphylococcal TSS presents with an abrupt onset of fever, chills, and severe gastrointestinal symptoms consisting of abdominal cramps; nausea; vomiting; and profuse, watery, nonbloody diarrhea. Occasionally, a prodrome consisting of low-grade fever, malaise, myalgia, or vomiting occurs in the week preceding the acute illness. Many children may also complain of a headache, myalgia, and a sore throat. At this stage of the illness, an incorrect diagnosis of acute viral gastroenteritis may be suspected. However, over the next 24 to 72 hours, a diffuse, blanching, macular erythroderma (sunburn-like) or scarlatiniform rash may appear. The rash may be faint or evanescent. The rash is not pruritic but is occasionally petechial. Patients demonstrate bilateral conjunctival hyperemia without discharge and may complain of photophobia. Oropharyngeal involvement includes a strawberry tongue or buccal ulcerations. Among adolescents, vaginal erythema with minimal clear watery discharge may be present in association with menstruation.

The case definition of staphylococcal TSS by the Centers for Disease Control and Prevention (CDC) is shown in Box 340-1.

Within 24 to 72 hours of onset, most patients with staphylococcal TSS experience orthostatic dizziness or syncope or both because of orthostatic hypotension. These symptoms can occur abruptly and may precede the development of hypovolemic shock. The peak of illness occurs on the second or third day and involves multiple organ systems. Central nervous system dysfunction may consist of headache, confusion, disorientation, hallucinations, or complaints of paresthesias of the hands and feet. Some patients have a stiff, tender neck. If a lumbar puncture is performed, cerebrospinal fluid is usually normal, although some patients may have up to 100 white blood cells/mm<sup>3</sup>, 50% of which may be polymorphonuclear cells. Abdominal musculature tenderness, absent or hypoactive bowel sounds, and radiologic evidence of a nonobstructive ileus are common. Common renal symptoms include azotemia, oliguria, and a diminished creatinine clearance; complete renal shutdown is rare. Exquisite muscle tenderness and severe myalgias are common. Arthralgias and joint effusions may be seen. Nonpitting edema over the wrists and ankles and synovitis of the small joints of the hands and feet have been reported. Patients may experience adult-type respiratory distress syndrome (shock lung). Hematologic involvement includes a progressive normochromic normocytic anemia, thrombocytopenia, and leukocytosis. Arrhythmias or prolonged shock may lead to eventual myocardial failure. Convalescence is characterized by a desquamation of the palms and soles within 1 to 2 weeks after the onset of illness. Some patients also experience hair and nail loss. Fatigue and weakness for as long as 3 months may occur in the recovery phase.

### BOX 340-1 Case Definition for Staphylococcal Toxic Shock Syndrome

- Fever: temperature:  $\geq 102.0^{\circ}\text{F}$  ( $38.9^{\circ}\text{C}$ )
- Rash: diffuse macular erythroderma; desquamation of palms and soles 1 to 2 weeks after onset of illness
- Hypotension: systolic blood pressure 90 mm Hg for adults or below fifth percentile by age for children under 16 years; orthostatic drop in diastolic blood pressure  $\geq 15$  mm Hg from lying to sitting, or orthostatic syncope
- Multisystem involvement—3 or more of the following:
  - Gastrointestinal: vomiting or diarrhea at onset of illness
  - Muscular: severe myalgia or creatinine phosphokinase level at least twice the upper limit of normal for laboratory
  - Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
  - Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria ( $>5$  white cells per high-power field) in the absence of urinary tract infection
  - Hepatic: total bilirubin, serum glutamic oxaloacetic transaminase, or serum glutamic pyruvate transaminase at least twice the upper limit of normal for laboratory
  - Hematologic: platelet count  $\leq 100,000/\text{mm}^3$
  - Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent
- Negative results on the following tests, if obtained:
  - Blood, throat, cerebrospinal fluid cultures; blood culture may be positive for *S aureus*
  - Antibody titer: Rocky Mountain spotted fever, leptospirosis, and rubeola

Adapted from Wharton M, Chorba TL, Vogt RL, Morse DL, Buehler JW. Case definitions for public health surveillance. *MMWR Recomm Rep*. 1990;39(Rr-13):1–43.

### Streptococcal Toxic Shock Syndrome

Streptococcal TSS is characterized by fever, rapid-onset hypotension, rapidly accelerated renal failure, and multisystem organ involvement, similar to staphylococcal TSS. Pharyngitis and local soft-tissue infection (eg, cellulitis, abscess, myositis, necrotizing fasciitis) associated with sudden severe pain is common with TSS. Pain, the most common initial symptom of streptococcal TSS, usually involves an extremity, but it may mimic peritonitis, pelvic inflammatory disease, or acute chest syndrome. Twenty percent of patients may have preceding influenza-like syndrome characterized by fever, chills, myalgia, nausea, vomiting, and diarrhea. Fever is the most common early sign, although hypothermia may be present in patients with shock. A diffuse scarlatina-like erythema occurs in only 10% of patients. Confusion is present in 55% of patients, and in some, coma or combativeness may occur.

### BOX 340-2 Streptococcal Toxic Shock Syndrome (*Streptococcus pyogenes*) 2010 Case Definition<sup>a</sup>

- Hypotension defined by a systolic blood pressure  $\leq 90$  mm Hg for adults or less than the fifth percentile by age for children aged younger than 16 years.
- Multi-organ involvement characterized by 2 or more of the following:
  - Renal impairment: creatinine  $\geq 2$  mg/dL ( $\geq 177$   $\mu\text{mol/L}$ ) for adults or greater than or equal to twice the upper limit of normal for age. In patients with pre-existing renal disease, a greater than twofold elevation over the baseline level.
  - Coagulopathy: platelets  $\leq 100,000/\text{mm}^3$  ( $\leq 100 \times 10^6/\text{L}$ ) or disseminated intravascular coagulation, defined by prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products.
  - Liver involvement: alanine aminotransferase, aspartate aminotransferase, or total bilirubin levels greater than or equal to twice the upper limit of normal for the patient's age. In patients with pre-existing liver disease, a greater than twofold increase over the baseline level.
  - Acute respiratory distress syndrome: defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia.
  - A generalized erythematous macular rash that may desquamate.
  - Soft-tissue necrosis, including necrotizing fasciitis or myositis, or gangrene.

<sup>a</sup>Clinical manifestations do not need to be detected within the first 48 hours of hospitalization or illness, as specified in the 1996 case definition. The specification of the 48 hour time constraint was for purposes of assessing whether the case was considered nosocomial, not whether it was a case or not.

From Centers for Disease Control and Prevention. Streptococcal toxic shock syndrome (STSS) (*Streptococcus pyogenes*) 2010 case definition. Available at: [wwwn.cdc.gov/nndss/conditions/streptococcal-toxic-shock-syndrome/case-definition/2010](http://wwwn.cdc.gov/nndss/conditions/streptococcal-toxic-shock-syndrome/case-definition/2010). Accessed February 3, 2016.

The case definition for streptococcal TSS is shown in Box 340-2.

Soft-tissue swelling and erythema is present in 80% of patients with streptococcal TSS, and up to 70% can progress to necrotizing fasciitis or myositis and will require surgical debridement, fasciotomy, or amputation. Necrotizing fasciitis is a life-threatening soft-tissue infection primarily involving the superficial fascia with a relative sparing of the skin and muscles, both of which may be infected secondarily. The patient may have a history of soft-tissue injury from an animal or insect bite, blunt or penetrating trauma, surgical wounds, or subcutaneous injections of insulin or illicit drugs. Streptococcal TSS may occur after varicella infection; 15% to 30% of invasive GAS diseases were reported to be associated with varicella. In some instances, an inconsequential scratch or abrasion may be implicated. Most patients have an

erythematous, tender, swollen area that resembles cellulitis with disproportionately severe pain at the site of involvement. An ominous sign of necrotizing fasciitis is the progression of soft-tissue swelling to the formation of vesicles, then bullae, which seem violaceous or hemorrhagic. The line of demarcation becomes sharply defined, and the dead skin begins to separate at the margins or breaks in the center, revealing an extensive necrosis of the subcutaneous tissue. The presence of crepitus on physical examination or soft-tissue air by plain-film radiograph, which is pathognomonic for necrotizing soft-tissue infections, is seen in only one-third and one-half of cases, respectively.

Severe pain, swelling, erythema, and fever may be the early signs of myositis. Pain is often out of proportion to the clinical findings, possibly related to muscle compartment syndrome, which may develop rapidly. Both necrotizing fasciitis and myositis are difficult to diagnose; therefore, clinical acumen and suspicion are important. Some patients with streptococcal TSS may have both necrotizing fasciitis and myositis. Emergent surgical exploration should be performed to establish and distinguish GAS infection from other soft-tissue infections. Nearly one-half of patients with streptococcal TSS may have normal blood pressure at the time of admission but soon develop hypotension. The presence of hypotension is a significant risk factor for death.

Renal dysfunction, which may occur before or after hypotension, progresses or persists in all patients for 48 to 72 hours in spite of treatment, and many patients require dialysis. In patients who survive, serum creatinine values return to normal within 4 to 6 weeks. Acute respiratory distress syndrome occurs in one-half of the cases and generally develops after the onset of hypotension. Profuse watery diarrhea, vomiting, abdominal pain, generalized erythroderma, conjunctival injection, and severe myalgias that are commonly present with staphylococcal TSS are present but less common with streptococcal TSS. Streptococcal TSS also may be associated with invasive GAS infections, such as pneumonia, meningitis, peritonitis, osteomyelitis, bacteremia, or septic arthritis. However, streptococcal TSS may occur without a readily identifiable focus of infection in 21% of cases. Recurrent episodes have not been reported for streptococcal TSS.

### Laboratory Evaluation

No single laboratory test confirms the diagnosis of TSS. Initial laboratory findings often include mild leukocytosis, but the mean percentage of immature neutrophils can reach 40% to 50%. Leukopenia has occasionally been observed in children with TSS. Progressive anemia and thrombocytopenia are often observed. Thrombocytopenia may be accompanied by the prolongation of prothrombin time and partial thromboplastin time and the appearance of increased fibrin split products. However, serious bleeding during the acute phase or thrombosis secondary to rebound thrombocytosis during recovery is uncommon. Most patients have hypoproteinemia and hypoalbuminemia, probably as a result of increased capillary

**Figure 340-1** A plain radiograph of an adolescent with necrotizing fasciitis reveals soft tissue air in the perineal region and the left abdominal wall (Courtesy of Shipra Gupta, MD, Children's Hospital of Michigan).

permeability caused by exotoxin-mediated vascular cell membrane change. A significant number of patients also experience lactic acidosis from inadequate tissue perfusion. Hyponatremia, hypokalemia, hypocalcemia, hypophosphatemia, and hyperglycemia are also noted. Renal involvement is indicated by the presence of hemoglobinuria and by rising serum creatinine values. Renal impairment precedes hypotension in 40% to 50% of patients. The serum creatinine kinase level is useful in detecting deeper soft-tissue infections; when the level is increased, a good correlation exists with necrotizing fasciitis or myositis. Hepatic enzyme and bilirubin levels are typically elevated initially but tend to revert to normal in convalescence. Blood cultures are generally negative for staphylococcal TSS, whereas blood cultures are positive for GAS in 60% of streptococcal TSS cases; however, the presence or absence of GAS bacteremia does not affect the mortality. Subcutaneous fluid may be aspirated from the affected limb for Gram stain and culture. All tissues obtained at the time of initial surgical debridement should be subjected to Gram staining and to culturing for aerobic and anaerobic microorganisms. Rapid antigen detection tests for GAS have not been approved for any specimen besides pharyngeal swab specimens; however, GAS may be identified from necrotic tissue with a rapid antigen test. In children with necrotizing soft-tissue infections, GAS is identified as a single organism in only 25% of cases; the remaining cases are polymicrobial.

### Imaging Studies

The use of imaging studies depends on clinical presentations. Such studies are more useful in the diagnosis of streptococcal TSS. The presence of soft-tissue air at the affected area may be observed in plain films (Figure 340-1). Computed tomography and magnetic resonance imaging also aid in the diagnosis of necrotizing fasciitis and myositis and in the delineation of the extent of infection. Features that indicate necrotizing fasciitis by computed

**Figure 340-2** Magnetic resonance imaging of a shoulder of a child with toxic shock syndrome shows significant enhancement of soft tissue and muscles with fluid tracking along the fascia (Courtesy of Shipra Gupta, MD, Children's Hospital of Michigan).

tomography or magnetic resonance imaging include deep fascial thickening and enhancement and the presence of fluid and gas in the fascial planes (Figure 340-2). The typical radiologic findings of myositis are of a general homogenous enlargement of the muscle, with low attenuation values and edema or the presence of intramuscular gas. It should be emphasized that imaging studies are only adjuncts in the evaluations of patients with TSS and necrotizing soft-tissue infections, and they should not be relied on to exclude the diagnosis or to delay surgical interventions. The diagnosis of invasive infection, including TSS, is still based primarily on clinical assessment.

## TREATMENT

The main treatment of a child with TSS includes hemodynamic stabilization, therapeutic support for multiorgan failure, and specific antibiotic therapy. A thorough search for possible sites of infections is mandatory to eliminate any preformed toxin and to prevent the synthesis of new toxins. Vaginal examination and removal of a tampon or other foreign body are mandatory. Surgical wounds should be considered as possible reservoirs of infection, even if no superficial signs of local infection are present. Infected wounds should be debrided, and any packing should be removed. Abscesses need to be drained and irrigated. Prompt and aggressive surgical exploration, fasciotomy, and debridement of suspected infection are mandatory. Culture specimens from all possible sites should be obtained. Surgical exploration and incisional biopsy, particularly in streptococcal TSS, provide both definitive diagnosis and treatment. Survival is possible with early surgical debridement, re-exploration at 24 to 36 hours, and intensive supportive

care. The extent of debridement is determined not only by the radiographic findings, but also by physical findings at the time of surgery.

Because TSS caused by *S aureus* and GAS is difficult to distinguish clinically, children suspected of having TSS should receive empiric, broad-spectrum antibiotic therapy with activities against both pathogens. The most commonly advocated antibiotic regimen includes the combination of expanded-spectrum penicillin or cephalosporins and clindamycin. As multidrug-resistant *S aureus* (MRSA) has emerged as an important pathogen in children, empiric antibiotic therapy that is effective against this pathogen should be considered. However, a recent study indicated a low prevalence of MRSA in TSS cases. The antibiotic regimen should be changed once the causative organism is identified. Antimicrobial therapy should be continued for at least 10 to 14 days to eradicate the organism and prevent recurrences. The total duration should also be based on the clinical improvement and the usual duration established for the underlying focus of infection.

Several pathophysiologic rationales support the use of combination antibiotic therapy of  $\beta$ -lactam and clindamycin for TSS. In patients with staphylococcal TSS, clindamycin has been shown to reduce TSST-1 production, whereas  $\beta$ -lactam antibiotics, including nafcillin and first-generation cephalosporins, increase TSST-1 in culture, probably by lysis or increased cell membrane permeability. Thus, the use of clindamycin in combination with a  $\beta$ -lactamase-resistant antistaphylococcal agent results in a potentially beneficial effect by decreasing the synthesis of TSST-1. In the setting of streptococcal TSS, penicillin is less efficacious in overwhelming GAS infections when large numbers of organisms are present (the so-called *Eagle effect*). Large inocula of GAS reach the stationary growth phase quickly, and penicillin is less efficacious against slowly growing organisms. Certain penicillin-binding proteins are not expressed by GAS during the stationary phase. The loss of penicillin-binding proteins may be responsible for the inocula effects observed and may account for the failure of  $\beta$ -lactam to control severe GAS infection. Conversely, the inhibitory effects of protein synthesis in clindamycin are independent of the inoculum size or the stage of bacterial growth. In addition, clindamycin suppresses the synthesis of bacterial toxins including the superantigens, facilitates phagocytosis of GAS by inhibiting M protein synthesis, has a postantimicrobial effect, and suppresses the synthesis of penicillin-binding proteins that, in addition to being targets for  $\beta$ -lactam, are also enzymes involved in cell-wall synthesis and degradation. Research has shown that clindamycin suppresses lipopolysaccharide-induced monocyte synthesis of tumor necrosis factor  $\alpha$ . The efficacy of the drug may thus also be related to its ability to modulate the immune response. A retrospective study demonstrated a favorable outcome among children with invasive GAS infections being treated with the combination of  $\beta$ -lactam and clindamycin. Clindamycin should not be used alone, because strains of *S aureus* or GAS with clindamycin resistance have been reported.

Intravenous immunoglobulin (IVIG) may be considered in children with TSS unresponsive to all other

therapeutic measures above. IVIG has been shown to reduce the morbidity and mortality of staphylococcal and streptococcal TSS, although most evidence was from streptococcal TSS. High levels of antibodies to TSST-1, streptococcal superantigens, and M proteins have been found in IVIG preparations. The usual dose of IVIG is 400 mg/kg over a period of 4 to 8 hours as a single dose. Staphylococcal superantigens are not inhibited as efficiently as streptococcal superantigens by IVIG, so a higher dose of IVIG may be required for therapy of staphylococcal TSS to achieve protective titers and clinical efficacy. The use of high-dose corticosteroids has sometimes been advocated as possibly beneficial in the treatment of shock syndromes. However, such therapy should not be administered routinely to patients with TSS, because it may result in a shorter time to defervescence and clinical stability while making no difference in overall risk of mortality. An association between the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and the development of TSS has been reported; this is likely because NSAIDs enhance the production of tumor necrosis factor. NSAIDs can impair granulocyte function and may mask signs of disease progression by relieving pain, reducing swelling, and suppressing fever, thus contributing to a delay in diagnosis.

Hyperbaric oxygen, a form of medical treatment in which the patient is enclosed in a chamber and breathes 100% oxygen at a pressure greater than 1 atmosphere absolute, has gained acceptance for treatment of a variety of medical conditions. Although a physiologic rationale can be found for the use of hyperbaric oxygen therapy in the treatment of necrotizing fasciitis, the results of clinical studies have been inconsistent. Some studies have shown that such therapy can improve patient survival and decrease the number of debridements required to achieve wound control, whereas others have shown no benefit.

## PREVENTION

### Staphylococcal Toxic Shock Syndrome

Primary prevention for menstrual staphylococcal TSS is achieved by encouraging limited use of high-absorbency tampons and educating the general public about the proper use of tampons and the importance of early recognition of TSS. If symptoms of TSS occur, tampons should be removed and prompt medical attention should be sought. Since as many as 30% of women who had menstrual TSS relapse during subsequent menstruation, tampon use in these women should be discontinued. Nonmenstrual staphylococcal TSS can be prevented by proper infection-control practices in surgical procedures and burn wound care. Vaccination against influenza should prevent influenza-associated staphylococcal pneumonia, an important cause of staphylococcal TSS.

### Streptococcal Toxic Shock Syndrome

Opportunities for preventing streptococcal TSS are few. Because of the association between invasive GAS infections, including TSS and varicella infection, in healthy children, routine childhood immunization against varicella is recommended by the AAP. Children who receive the varicella vaccine are less likely to

be hospitalized for varicella-related invasive GAS infections. A relationship between the use of NSAIDs and necrotizing fasciitis has been reported. Evidence suggests that NSAIDs can impair granulocytic function and enhance production of cytokines. Although some physicians have suggested that NSAIDs should not be used to treat children with varicella, a causal relationship between NSAID use and severe invasive GAS infections has not been established. Nosocomial GAS infections should be prevented by improving infection-control practices for surgical and obstetric procedures and for placement and care of intravascular devices.

GAS can easily spread through the household. In many of these clusters, additional family members, usually children, are identified with pharyngitis or with carriage of the same strain of GAS that caused the invasive disease. The relative risk of invasive GAS infections among household contacts of patients with invasive GAS infections are 19 to 200 times the baseline risk in the general population. Secondary cases of invasive GAS infections, including STSS within the same household, have been reported. Although the risk of subsequent invasive GAS disease among household contacts is higher than the risk among the general population, such infections are rare. No studies have evaluated the effectiveness of chemoprophylaxis in preventing invasive GAS disease among household contacts of patients with invasive GAS infections; thus, routine chemoprophylaxis among household contacts is not warranted. Health care providers should inform members of the household about the clinical manifestations of pharyngeal and invasive GAS infections and emphasize the importance of seeking immediate medical attention if they develop such symptoms, particularly within 30 days after the diagnosis is made in the index case. Routine use of cultures to identify household contacts who are colonized with GAS is not suggested.

Because of the high mortality rate associated with invasive GAS infections in persons older than 65 years and those with underlying illnesses or other host factors, chemoprophylaxis to prevent secondary cases may be offered to household members aged 65 years or older and those with human immunodeficiency virus infection, concurrent varicella infection, diabetes mellitus, cancer, chronic cardiac or pulmonary diseases, injection drug use, alcoholism, known immunodeficiency disorder, or corticosteroid use. Because the source of GAS in households is not necessarily the person with invasive infection, physicians who elect to prescribe chemoprophylaxis for an elderly or high-risk household member should prescribe chemoprophylaxis for all members in that household. If available, antibiotic susceptibility data should be used to select the most appropriate chemoprophylactic agent. Everyone who receives chemoprophylaxis should watch for signs and symptoms of invasive GAS disease for 30 days after the diagnosis of invasive disease in the index case. The chemoprophylactic regimens are as follows:

1. A single dose of benzathine penicillin G (600,000 units intramuscularly for persons weighing <27 kg or 1,200,000 units intramuscularly for persons weighing  $\geq$ 27 kg) and oral rifampin 20 mg/kg/day

(maximum daily dose, 600 mg) in 2 divided doses for 4 days

2. Clindamycin 20 mg/kg/day (maximum daily dose, 900 mg) in 3 divided doses for 10 days
3. Azithromycin 12 mg/kg/day (maximum daily dose, 500 mg) once a day for 5 days. It should be noted that a significant proportion of GAS strains have been reported as being resistant to macrolides, including azithromycin.

There is limited evidence that first- and second-generation cephalosporins are effective in eradicating the pharyngeal colonization of GAS, and these agents could be considered for patients who are allergic to penicillin whose allergic reactions are not anaphylactic. Rifampin is not recommended for pregnant women because of its teratogenic effect.

Enhanced surveillance by infection control personnel should be implemented after identifying a case of postpartum or postsurgical invasive GAS infection. All GAS isolates from suspected cases should be stored and compared by serotyping or molecular techniques. The occurrence of 2 or more cases of invasive GAS infection by the same GAS type within a 6-month period suggests that a health care worker might be the source of the cluster; therefore, it is strongly recommended that health care workers who are epidemiologically linked to the case patients be screened by obtaining cultures from throat, anus, vagina, and skin lesions. One of the 3 prophylactic regimens mentioned above can be prescribed to health care workers who are colonized with GAS. Follow-up culture should be performed 7 to 10 days after the completion of therapy.

### WHEN TO REFER

All children with TSS should be managed by a multidisciplinary team of pediatric critical care specialists, pediatric infectious diseases specialists, and pediatric surgeons.

### WHEN TO ADMIT

All children with TSS should be admitted.

## Chapter 341 TUBERCULOSIS

Ann M. Loeffler, MD; Mark N. Lobato, MD

Tuberculosis (TB) is a serious disease caused by *Mycobacterium tuberculosis* complex. TB disproportionately affects young children as a result of their increased risk for progression to disease when infected by *M tuberculosis* and the increased likelihood of disseminated disease. In the United States, children who are at the highest risk for TB are children of color, children born in countries with a high prevalence of TB or into families from these countries, children who live with or in contact with adults who are at risk for TB, and children younger than 4 years of age.

## DEFINITIONS

### Tuberculosis

Tuberculosis is caused by infection with an organism of the *M tuberculosis* complex, which includes *M tuberculosis* and *Mycobacterium bovis*, and is distinguished from latent TB infection (LTBI). Common clinical presentations of TB include pneumonia, pleuritis, intrathoracic or peripheral lymphadenopathy, meningitis, disseminated TB, and bone and joint disease. In the United States, children diagnosed with TB disease are often asymptomatic but have radiographic evidence of disease such as an infiltrate or intrathoracic adenopathy. Asymptomatic presentations of TB disease are treated with multidrug therapy because they will progress in many children if not treated. Table 341-1 provides epidemiologic data for TB in children. Among the 460 US children 0 to 14 years of age with TB in 2014, 262 were younger than 5 years, 198 were ages 5 to 14 years; 41% were Hispanic, and 23% were black. A total of 22% of TB cases in children occurred in the foreign born with Mexico being the leading country of birth. From 1993 to 2014, TB case rates declined from 2.9 to 0.8 cases per 100,000 children. Forty percent of the cases reported were from California, Texas, and New York.

### Latent Tuberculosis Infection

Latent infection with *M tuberculosis* complex occurs when the organism is in a metabolically slower state and replicating slowly within granulomata in the lung

or other tissues. The patient usually has a positive tuberculin skin test (TST) result or a positive interferon- $\gamma$  (IFN- $\gamma$ ) release assay (IGRA) blood test result but no clinical or radiographic evidence of TB disease (although evidence of healed disease such as calcified nodes may be present). Patients should be treated with isoniazid (isonicotinylhydrazine [INH]) monotherapy daily for 9 months, unless they have a medical contraindication (including infection with a known INH-resistant strain). Because LTBI is not a reportable condition in most states, the number of children who have LTBI can only be estimated.

**Table 341-1** Tuberculosis (TB) Among Children, United States, 2014

GROUP	TB CASE RATE PER 100,000 CHILDREN
Children ages 0–14 yr	0.8
Children <5 yr	1.3
Hispanic or Latino	2.1
Asian	5.0
Black or African American	2.1
White	0.3

Atlanta, Ga: US Department of Health and Human Services, Centers for Disease Control and Prevention; October 2014. Available at: [www.cdc.gov/tb/statistics/reports/2014/default.htm](http://www.cdc.gov/tb/statistics/reports/2014/default.htm).

### Tuberculosis Exposure

A person exposed to TB is one who has spent time in close proximity to a potentially contagious patient with pulmonary TB disease. The exposed individual may or may not be infected. Because young children can progress rapidly to TB once infected, they should be quickly evaluated and receive prophylactic treatment if found to be exposed to an individual with TB.

### DIFFERENTIAL DIAGNOSIS

TB symptoms mimic many different diseases. Because TB is uncommon in the United States among most populations, the pediatrician must maintain a high index of suspicion for TB, especially among children who fit the epidemiologic profile and who have risk factors for infection and disease. The differential diagnosis for TST results is outlined in Box 341-1. The differential diagnosis for forms of TB disease is provided in Box 341-2.

### Testing for Tuberculosis Infection

The American Academy of Pediatrics (AAP) does not recommend universal testing for TB. Assessment at the first visit and annually thereafter for TB risk factors and testing of children with defined risk factors is the standard of care. Testing asymptomatic children without known risk factors for TB is no longer performed. The TST and IGRA are used to diagnose LTBI and support the diagnosis of TB disease. Because of the poor sensitivity and specificity of the TST in low-incidence populations, it is given only to children identified as having increased risks for TB exposure or

### BOX 341-1 Differential Diagnosis for Tuberculin Skin Test Results

#### TRULY POSITIVE

- Caused by infection with *M tuberculosis* complex

#### FALSELY POSITIVE

- Cross-reaction with nontuberculous mycobacteria, such as *M avium* complex and *Mycobacterium scrofulaceum*. These reactions are often, but not always, smaller than those caused by *M tuberculosis*.
- Cross-reaction with a recent or multiple vaccinations with BCG. In general, the public health strategy in the United States is to discount the history of BCG vaccination when deciding to administer or interpret the TST. If a patient has received only a single BCG vaccination in the newborn period and a year has elapsed since the last BCG, then a positive TST reaction resulting from BCG is unlikely.
- Allergic-type reactions. These reactions peak within 24 hours of TST placement and should resolve within 48–72 hours. Induration that peaks >24 hours after TST placement is caused by a delayed-type hypersensitivity, the mechanism of a true positive TST reaction.

- Irritation from a circular bandage or tape
- Injection with a substance other than PPD
- Incorrect interpretation of reaction

#### FALSELY NEGATIVE

- Recent infection with *M tuberculosis* (delayed-type hypersensitivity reaction takes 2–8 weeks after infection to develop)
- Infants age <6 months
- Improper storage of the PPD skin test material (eg, not refrigerated, prolonged storage in syringe)
- Improper placement (eg, subcutaneous placement, pressure by gauze or a bandage leading to the absorption of PPD solution)
- Vaccination with a live virus vaccine within the previous 6 weeks
- Generalized or specific anergy associated with extensive or disseminated TB or as seen in immunocompromised patients, especially those infected with HIV
- Incorrect interpretation of reaction

BCG, bacille Calmette-Guérin; PPD, purified protein derivative; TB, tuberculosis; TST, tuberculin skin test.

### BOX 341-2 Differential Diagnosis for Forms of Tuberculosis Disease

#### PULMONARY INFILTRATE

- Community-acquired pneumonia (ie, bacterial pneumonia, including lung abscess and necrotizing pneumonia; viral pneumonia)
- Atelectasis caused by reactive airways disease or other processes
- Other granulomatous diseases (eg, coccidioidomycosis, histoplasmosis)
- Anatomic, foreign body, and structural disorders

#### INTRATHORACIC LYMPHADENOPATHY

- Infections caused by fungus, virus, or bacteria
- Nontuberculous mycobacterial infections
- Malignancies
- Round pneumonia
- Other granulomatous diseases (eg, coccidioidomycosis, histoplasmosis)

#### SUBACUTE PERIPHERAL ADENOPATHY

- Nontuberculous mycobacteria
- Cat-scratch disease
- Toxoplasmosis
- Partially treated pyogenic infection

#### MENINGITIS

- Viral, bacterial, fungal, and chemical meningitis

disease. A TST or IGRA should be undertaken only for children who have clinical disease that raises concern for TB, children at high risk for progression to TB disease, and children who have new risk factors for TB exposure since their last test. Most children with US-born parents never require a TST or IGRA.

In the United States, the only recommended TST is intradermal instillation of 5 TU (0.1 mL) purified protein derivative (PPD) by the Mantoux method. The skin test should be administered and interpreted by a trained health care professional. The definition of a positive TST result depends on risk factors for infection and the likelihood of TB disease. Box 341-3 lists the breakpoints used to interpret TB skin test results in children.

In areas with low TB rates, most positive TST reactions are in fact falsely positive. (See Box 341-1 for details.) If a child is found to have a positive TST or IGRA result, the evaluation includes a chest radiograph, focused history, and physical examination. A 2-view chest radiograph (frontal and lateral views) is particularly helpful in differentiating intrathoracic lymphadenopathy from other hilar structures. National guidelines suggest obtaining 2-view radiographs on all children when resources permit. If resources are limited, children older than 6 years can be screened with 1-view chest radiographs.

Targeted testing is the strategy of testing only children who are at high risk for contracting infection with *M tuberculosis* or developing TB disease once infected. This strategy results in fewer unnecessary

### BOX 341-3 Breakpoints for Interpretation of Tuberculin Skin Test Results

A  $\geq 5$ -mm induration is interpreted as positive in the following circumstances:

- Child is a recent contact of a person with TB or suspected TB disease
- Child is immunosuppressed (receiving immunosuppressive therapy) or immunocompromised, including HIV infection
- Radiograph or clinical evidence suggests TB disease
- Calcified granuloma on chest radiograph are consistent with prior TB infection

A  $\geq 10$ -mm induration is interpreted as positive in the following circumstances:

- Child is  $<4$  years of age
- Child has medical conditions (eg, lymphoma, Hodgkin disease, diabetes mellitus, chronic renal failure, malnutrition)
- Child or parent was born in a country with a high prevalence of TB
- Child has frequent exposure to high-risk adults (HIV infected, homeless, residents of nursing homes, institutionalized, incarcerated, users of illicit drugs, migrant farm workers)
- Child has traveled to a high-prevalence country

A  $\geq 15$ -mm induration is interpreted as positive in the following circumstance:

- Child is  $\geq 4$  years of age and has no risk factors

TB, tuberculosis.

Adapted from American Academy of Pediatrics. Tuberculosis. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:805–831.

tests and avoids evaluation and treatment of children with false positive test results. At each well-child visit, the child should be screened with a risk-factor questionnaire. The child should undergo testing only if a new risk factor has been identified since the last test. Foreign birth, foreign travel, and close contact with individuals with a positive TST or IGRA result or TB disease predict increased risk for LTBI. Individual questionnaires should be modified based on local risks. A sample questionnaire is provided in Box 341-4, and the general strategy for targeted TB testing is outlined in Figure 341-1.

Prior bacille Calmette-Guérin (BCG) vaccination sometimes causes a small, transient TST reaction as a result of cross-reactivity among antigens. The effect of BCG vaccination on TST reaction is an ongoing challenge for pediatricians. The Centers for Disease Control and Prevention and the AAP advise pediatricians to discount the history of BCG vaccination when interpreting the TST. The following factors decrease the likelihood that the skin test reaction is caused by BCG:

- TST reaction (induration)  $>10$  mm
- Previous receipt of a single rather than multiple BCG vaccines
- BCG given in the first month of life

**BOX 341-4 Tuberculosis Risk Assessment Questionnaire**

Name: \_\_\_\_\_ DOB: \_\_\_\_\_

Last test:

TST date: \_\_\_\_\_ Results: \_\_\_\_\_ mm induration OR \_\_\_\_\_ not read by health care professional

IGRA date: \_\_\_\_\_ Results: \_\_\_\_\_

If positive TST or IGRA result in the past, chest radiograph date and result: \_\_\_\_\_

1. Was your child born outside the United States? \_\_\_\_\_ Yes \_\_\_\_\_ No  
Country: \_\_\_\_\_
2. Since the last TST or IGRA, has your child traveled outside the United States? \_\_\_\_\_ Yes \_\_\_\_\_ No  
Country or countries visited: \_\_\_\_\_  
Dates of travel and how long did the child travel? \_\_\_\_\_  
Where did the child stay (hotel, family, resort)? \_\_\_\_\_
3. Since the last TST or IGRA, has your child been exposed to anyone with TB disease? \_\_\_\_\_ Yes \_\_\_\_\_ No  
Name of the person's disease: \_\_\_\_\_  
Did the person have a positive TST or IGRA result with normal chest radiograph taking 1 medicine or no treatment OR TB disease taking many pills and different kinds of medicine?  
Name of person: \_\_\_\_\_ DOB: \_\_\_\_\_  
Where is the person being treated? \_\_\_\_\_
4. Since the child's last skin test, has your child had close contact with a person who has a positive TST result? \_\_\_\_\_ Yes \_\_\_\_\_ No  
Nature of the person's disease: \_\_\_\_\_  
Did the person have a positive TST result with normal chest radiograph taking medicine or no treatment OR TB disease taking many pills and different kinds of medicine?  
Name of person: \_\_\_\_\_ DOB: \_\_\_\_\_  
Where is the person being treated? \_\_\_\_\_

Optional questions depending on local epidemiology:

Since the last TST or IGRA, has your child consumed unpasteurized milk or cheese (from Mexico or Central America)? \_\_\_\_\_ Yes \_\_\_\_\_ No

Since the last TST or IGRA, has your child been around people in jail, people who were homeless or in shelters, people who have HIV or use illegal drugs? \_\_\_\_\_ Yes \_\_\_\_\_ No

Since the last TST or IGRA, has your child lived with a new person who was born or traveled outside the US? \_\_\_\_\_ Yes \_\_\_\_\_ No

INSTRUCTIONS FOR PROVIDERS: Test only children who have a new risk factor since their last TST or IGRA.

If the child has previously had a positive TST or IGRA result, then do not administer another test.

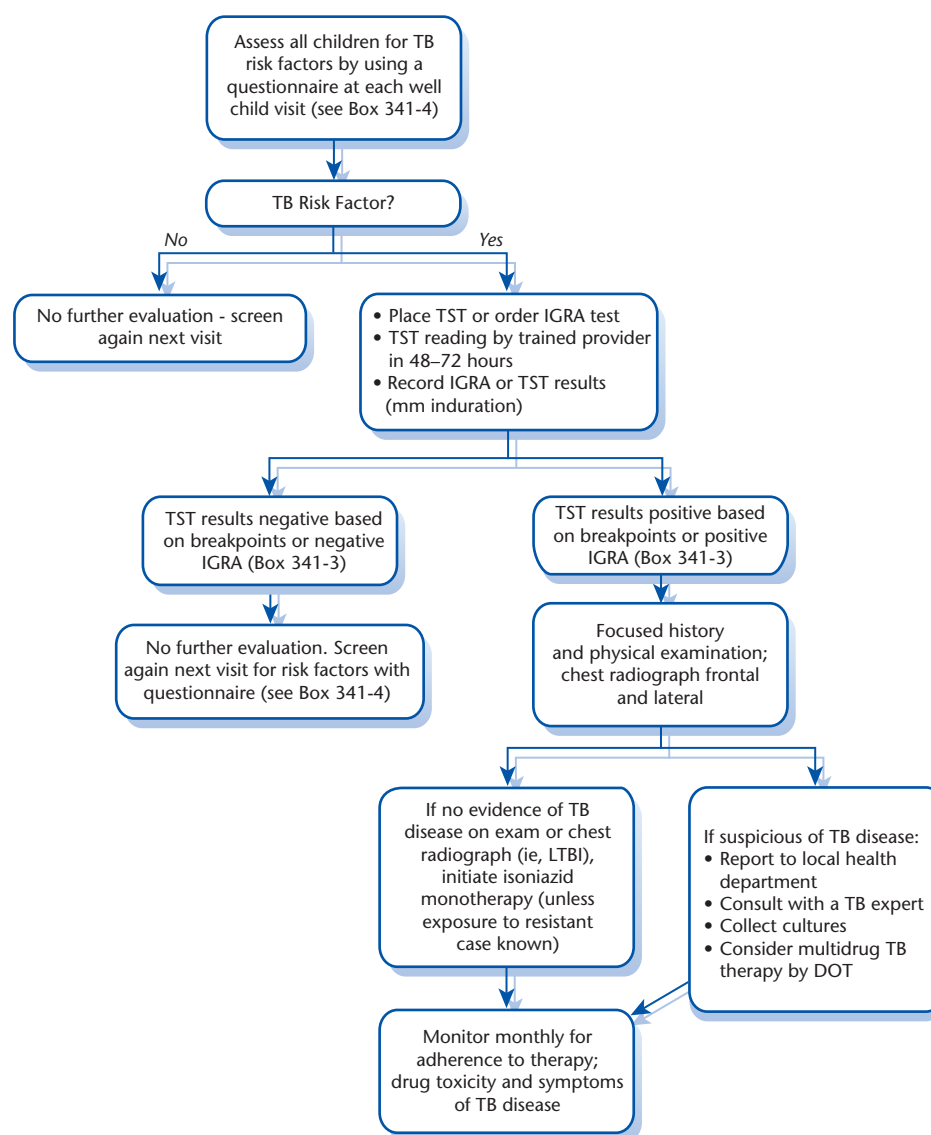

Significant travel is considered travel to a country with a high prevalence of TB (eg, in Africa, Asia, Latin American, and Eastern Europe) for >1 week AND had a substantial contact with indigenous people from such countries (did not stay in a resort).

Adapted from Pediatric Tuberculosis Collaborative Group. Targeted tuberculin skin testing and treatment of latent tuberculosis infection in children and adolescents. *Pediatrics*. 2004;114:1175–1201.

- A long period since the BCG dose
- Receipt of no other recent TST

The IGRA tests are *in vitro* diagnostic tests for detecting either IFN- $\gamma$  production directly when a patient's whole blood is incubated with antigens that are fairly specific to *M tuberculosis* complex and controls, or by enumerating sensitized T cells that release IFN- $\gamma$  in the vicinity of the T cells. The detection of IFN- $\gamma$  or sensitized T cells indicates a response by the patient's lymphocytes and probable infection with *M tuberculosis*. During the past several years, many IGRA studies have

been done or are underway supporting their use in children and adolescents. As with TSTs, IGRAs cannot distinguish between LTBI and TB disease. A negative result from these tests cannot exclude the possibility of TB disease. A number of studies demonstrate that IGRAs perform well in most children 3 years of age or older. The sensitivity of these blood tests is comparable to that of TSTs for detecting *M tuberculosis* infection in older children who have culture-confirmed tuberculosis. The specificity of IGRAs is higher than that for TSTs because the antigens used are not found in BCG or most

**Figure 341-1** General strategy for targeted tuberculosis testing. DOT, directly observed therapy; IGRA, interferon-gamma release assay; LTBI, latent tuberculosis infection; TST, tuberculin skin test.

nontuberculous mycobacteria (eg, are not found in *M avium* complex). The correct interpretation of a negative IGRA test result in a child with a positive TST result is difficult because of the absence of longitudinal studies to determine the prognostic value of the IGRAs (especially when the TST result is positive).

Neither an IGRA nor the TST can be considered a “gold standard” for diagnosis of LTBI. Current AAP recommendations for use of IGRAs in children are as follows:

- Children with a positive result from an IGRA should be considered infected with *M tuberculosis* complex. A negative IGRA result cannot necessarily be interpreted as absence of infection.
- For immunocompetent children 5 years of age and older, IGRAs can be used in place of a TST to diagnose cases of LTBI or as an adjunct in diagnosing

cases of tuberculosis disease and likely will yield fewer false-positive test results.

- The 2015 AAP *Red Book* endorses use of IGRA tests in children as young as 3 years of age in the following circumstances:
  - Children with a negative TST, but high clinical suspicion for TB disease and/or high risk for infection, progression, or poor outcome
  - Children with a positive TST, but who are healthy with low risk for TB infection, when additional information is required to ensure adherence to LTBI treatment or the child is suspected of having nontuberculous mycobacterial disease
- Because of their higher specificity and lack of cross-reaction with BCG, IGRAs are the preferred test for children 5 years or older who have received BCG vaccine. If a TST already has been performed in

these children and is reactive, a negative IGRA is evidence against the diagnosis of LTBI but does not exclude infection.

- Negative IGRA results should be interpreted with caution in children younger than 3 years and in immunocompromised children of any age because of a relative lack of published data about test sensitivity among these groups.
- Indeterminate IGRA results, most often owing to a low mitogen response or improper handling, do not exclude *M tuberculosis* infection and should not be used to make clinical decisions. Consideration should be given to repeating the IGRA or performing a TST.

## MANAGEMENT

### Tuberculosis Exposure

A child exposed to an adult or adolescent with potentially contagious TB requires prompt and thorough evaluation to determine whether the child already has evidence of LTBI or TB disease. All exposed individuals should undergo a symptom review, testing with either a TST or an IGRA, and a focused history and physical examination. These evaluations should be coordinated with the local health department. Children younger than 5 years of age and all immunocompromised individuals with significant exposure should receive *window prophylaxis* after TB disease has been ruled out by a normal chest radiograph and negative physical examination. Window prophylaxis is the practice of treatment with INH until a repeat TST or IGRA is given 8 to 10 weeks after their last exposure (Figure 341-2) is performed and the result is negative.

### Latent Tuberculosis Infection

Management of LTBI is reasonably easy after TB disease is eliminated as a possibility. INH monotherapy should be initiated unless strong evidence exists of INH drug resistance in the source case (not merely LTBI acquisition in an area with a high level of INH resistance). Dosing is 270 daily doses (twice or three times a week administered by directly observed therapy [DOT]) within a 12-month period. Table 341-2 lists INH doses by weight. When a prolonged break occurs after a short initial treatment period, then therapy should be restarted, but short lapses are tolerated, especially if the regimen is well underway. If interruption of therapy is greater than 2 months, then the child should be reevaluated for possible TB disease before restarting INH. Vitamin B<sub>6</sub> (pyridoxine) supplementation is indicated only for exclusively breastfed infants, children and adolescents on milk- and meat-deficient diets, children who experience paresthesias while receiving isoniazid therapy, those with symptomatic HIV infection, and pregnant adolescents.

INH is available as 100-mg and 300-mg scored tablets and as a liquid suspended in sorbitol. The liquid formulation causes cramping and diarrhea in more than one-half of children because of its osmotic load. As an alternative, the tablet can be crushed and mixed with or layered into a strong-flavored semisoft food in a spoon. INH should be prescribed in monthly

allocations, with clinic visits scheduled for periodic (monthly or bimonthly) face-to-face monitoring for drug toxicity. INH-related transient increase of transaminases has been noted in children, with the effects increasing with increasing age; however, INH rarely causes clinical hepatotoxicity in children. Routine monitoring of liver transaminases is not indicated for asymptomatic children who do not have underlying liver disease and who are not receiving other hepatotoxic drugs. Families should be thoroughly educated about recognizing symptoms of hepatotoxicity (eg, anorexia, malaise, abdominal pain, vomiting) and instructed when to stop therapy and return to the clinic for assessment and possible laboratory testing. Lack of association with other viral symptoms and lack of improvement after a few days should suggest the possibility of hepatotoxicity rather than an intercurrent illness.

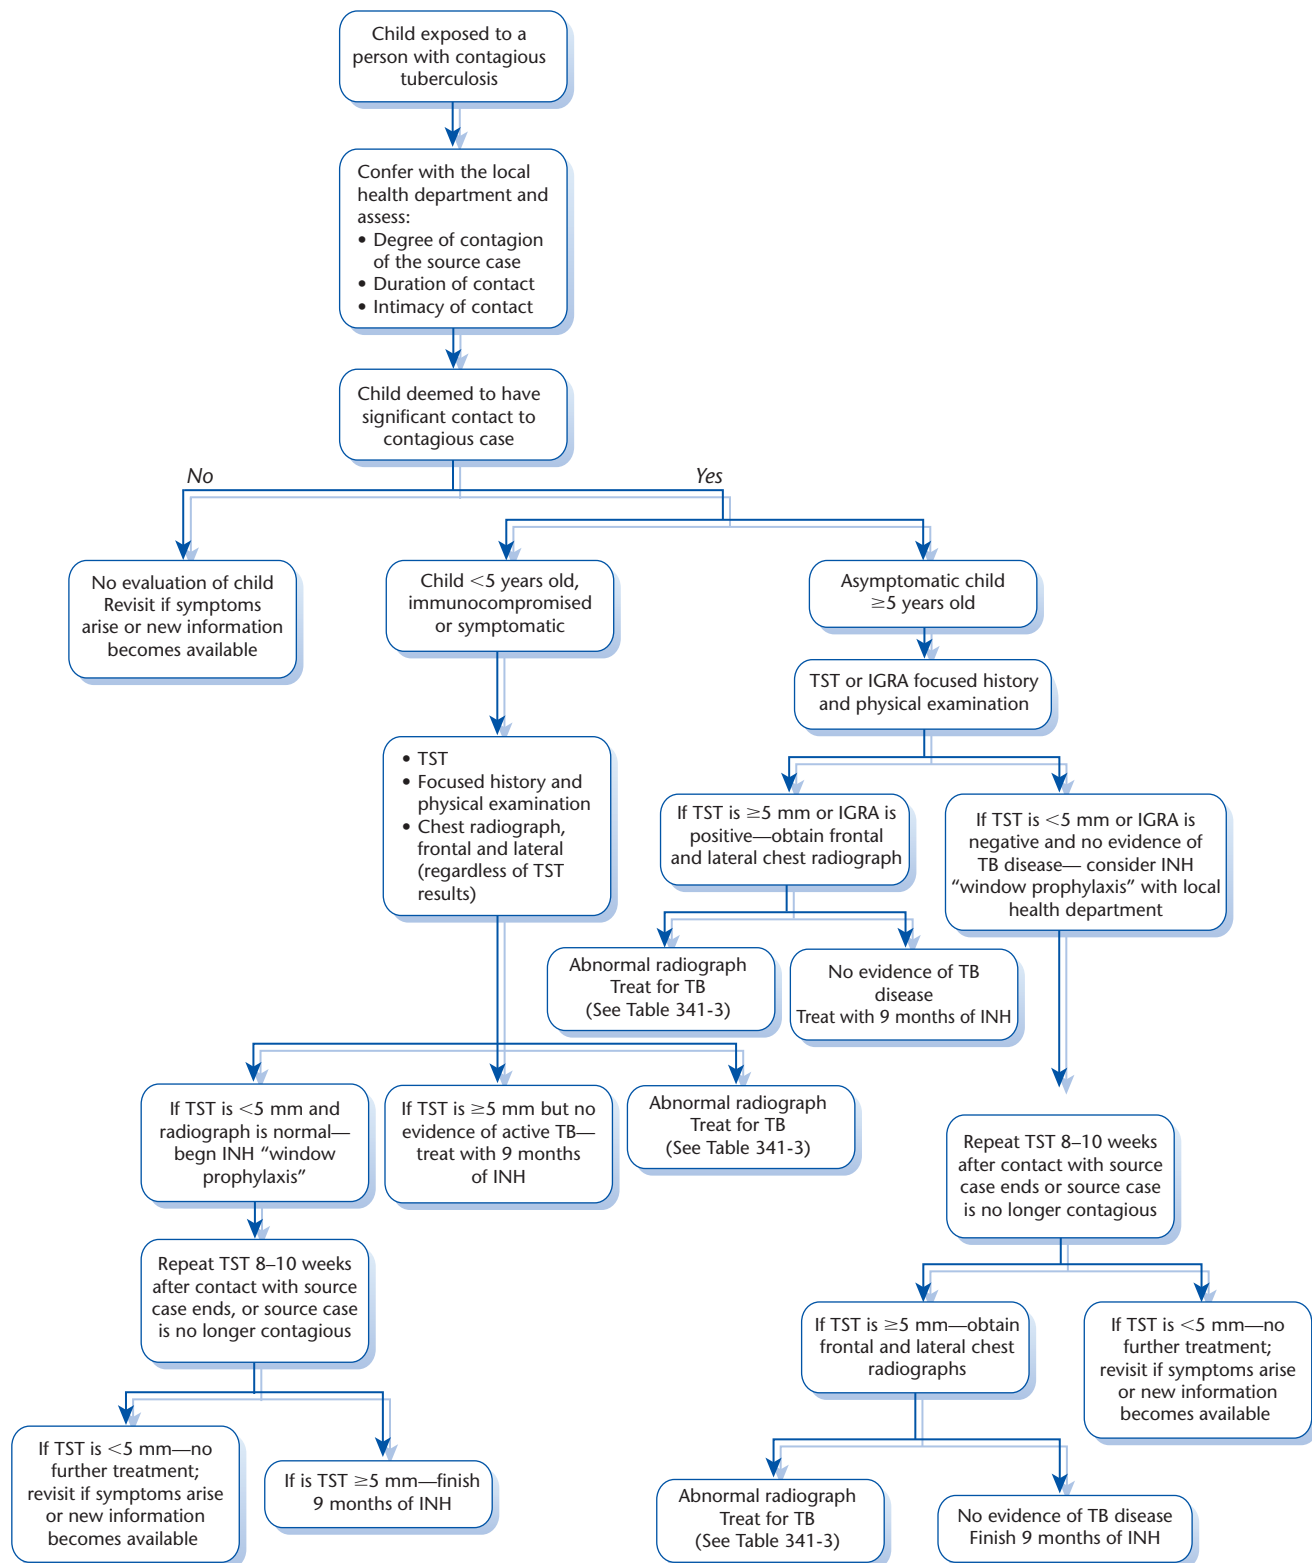

Caregivers should be asked about the child's adherence to therapy and results of testing with TSTs or IGRAs of family members and other contacts. Figure 341-3 shows an example of a flow sheet for monitoring LTBI treatment. Every effort should be made to promote and facilitate adherence through enablers such as walk-in visits for refills (nurse visits) or school-based dosing or monthly monitoring. Incentives such as stickers, prizes, and end-of-treatment rewards can also be used to promote adherence (eg, see [www.maine.gov/dhhs/mecdc/infectious-disease/epi/tuberculosis/treasure-chest.shtml](http://www.maine.gov/dhhs/mecdc/infectious-disease/epi/tuberculosis/treasure-chest.shtml)). Children receiving antiepileptic drugs (particularly phenytoin and carbamazepine) should be monitored closely because INH affects the drug levels of some of these medications.

After completing the 270 doses of INH for LTBI, the family should be provided with a card or letter documenting completion of therapy and reminded that the child should not undergo tuberculin testing in the future. An end-of-completion radiograph is not necessary.

Rifampin (10–20 mg/kg) given for 120 daily doses is occasionally used as an alternative for a patient who is intolerant to INH or is known to be infected by an INH-resistant TB strain. Most side effects of INH can be overcome with adjustments of timing or symptomatic management. Rifampin may accelerate the metabolism or have other interactions with several important classes of drugs, including anticonvulsants, antiarrhythmics, antifungals, barbiturates, beta blockers, calcium channel blockers, antibiotics, corticosteroids, oral contraceptives, oral hypoglycemics, and drugs used to treat HIV infection. Adjusting the dose of these drugs may be necessary if they are given concurrently with rifampin. Providers caring for children and adolescents receiving antiretroviral therapy should consult updates on drug interactions.

A newer LTBI regimen has undergone limited trials in young children, but was well studied in older children and adults. Once weekly INH and rifapentine by DOT for 12 doses is effective in preventing progression to TB disease. It is generally used for children 12 years and older, but has been used in younger children down to the age of 2 years.

Treatment of children infected by persons having multidrug-resistant TB (resistance to both INH and rifampin) should be done in consultation with a pediatric tuberculosis specialist.

**Figure 341-2** Evaluation of a child exposed to a person with contagious tuberculosis. *IGRA*, interferon-gamma release assay; *INH*, isoniazid; *TST*, tuberculin skin test.

>20	>44	300	0	1

<sup>a</sup>Maximum dose, 300 mg.

## EVALUATION

### History

Evaluation is intended to discern TB disease from LTBI, as well as to identify a possible source of infection, risks for drug resistance, and underlying medical conditions that might increase the risk for TB or complicate TB treatment (Figure 341-4).

In the United States, approximately one-half of children diagnosed with TB disease either have no symptoms or their symptoms have been developing so subtly and insidiously that their parents have not noticed. Common symptoms include weight loss or failure to gain weight, anorexia, fever, and cough, as well as decreased energy, playfulness, or activity. Other symptoms may be noted for patients with extrapulmonary TB: lymph node enlargement, headache, personality changes, focal neurologic changes, or musculoskeletal pain. TB can produce fulminant or indolent symptoms, but symptoms are typically more chronic when caused by TB than when caused by bacterial or viral infections. Cough is often noted for weeks rather than days; lymph node swelling develops over weeks, with gradual and modest changes in the overlying skin. Occasionally, symptoms such as cough and fever are actually improving at the time of diagnosis.

The history should include information that would suggest an alternative diagnosis, such as reactive airways disease, bacterial or viral pneumonia, pyogenic lymphadenitis, or viral meningitis. Pertinent medical history includes previous TST or IGRA results, previous TB treatment, and results of any previous chest radiographs. The medical history should also include factors that would complicate TB therapy, including underlying liver disease and use of potentially hepatotoxic drugs. Patients infected with HIV or who have another immunocompromising condition are more likely than others to have TB and are more likely than others to have an atypical or extrapulmonary presentation of TB.

Close contact to a contagious person results in a significant proportion of household contacts becoming infected. If the family knows of a TB exposure, then the history should include the name, address, and date of birth of the patient with TB, as well as the jurisdiction of treatment, susceptibility data, and treatment details.

If the family does not know anyone with TB disease, then family members should be asked whether they have close contact with an adolescent or adult with

chronic cough, fever, or unexplained weight loss or if they have household contact with an individual with a positive TST or IGRA result (especially a newly positive result). Because almost two-thirds of adult patients with TB disease are born outside the United States (primarily in Latin America, Asia, Africa, and Eastern Europe), contacts including visitors and caregivers from these areas should be solicited. Children who were born in an area with a high incidence of TB or who have traveled to these areas are at increased risk for TB and LTBI. Family members should be asked where children were born, where they have traveled, how long they stayed, and with whom they stayed when traveling in TB-endemic areas.

Ingestion of foreign unpasteurized milk and milk products, such as Mexican-style soft cheeses (queso fresco), raises the possibility of infection with *M bovis* (although *M bovis* has a propensity to cause peripheral and intraabdominal lymphadenitis, it can cause any TB manifestation, including pneumonia).

Finally, if several family members have positive TST or IGRA results, then the likelihood that the child's disease is TB increases. The pediatrician should perform a TST or IGRA on any family member who has not recently undergone such a test (and has never had a positive result in the past). To prevent possible continued transmission of TB, chest radiographs of adults with a previous or newly positive TST or IGRA result or suspicious TB-like symptoms should be obtained in conjunction with the local health department.

### Physical Examination

The focused physical examination should emphasize vital signs, growth parameters, conjunctival examination, neck flexion, lymph node palpation, auscultation of heart and lungs, abdomen and flank palpation, spine and bone palpation, brief skin examination, and neurologic examination (depending on concerns for TB of the central nervous system). Children diagnosed as having LTBI will have no examination abnormalities that suggest TB disease. Even children with pulmonary TB may have no findings at physical examination. The findings on chest radiograph are often more useful than those found by physical examination.

### Laboratory Evaluation

Routine testing for children suspected of having TB includes HIV serologic testing and mycobacterial

cultures. Sputum specimens are challenging to collect from young children, but they can be collected by gastric aspiration (Box 341-5), induction, or bronchoalveolar lavage. Gastric aspirates are typically collected on 3 consecutive mornings after an overnight fast. Historically, yields are between 30% and 50%, with the highest yields being in the youngest infants and from the initial sample collected. If the child is not otherwise ill

enough to require inpatient management, then gastric aspirates can be collected in the outpatient setting.

In older children, sputum induction with hypertonic saline should be attempted; inducing sputum in infants is difficult. Bronchoalveolar lavage is used primarily when diagnostic possibilities other than TB are being strongly considered. Yield for bronchoalveolar lavage in culturing *M tuberculosis* in children is

**Figure 341-4** Evaluation of a child with a positive TST or IGRA result. *IGRA*, interferon-gamma release assay; *LTBI*, Latent tuberculosis infection; *TST*, tuberculin skin test.

between 10% and 21%, and yields are generally less than that for gastric lavage in children.

Guided by the physical examination and clinical scenario, other specimens may be collected, including cerebrospinal fluid (CSF). CSF culture has a 50% to 75% yield in diagnosis of TB meningitis. Acid-fast bacillus (AFB) smear has an even lower yield, but it can be improved by centrifugation of large volumes of CSF. The use of the polymerase chain reaction technique has been disappointing, but it may play a role as an adjunct diagnostic method. AFB smear and culture

of other tissues should be undertaken as indicated for lymph node tissue, abscess drainage, bone or synovial fluid, urine, blood, bone marrow, or other tissue. Specimens for AFB smear and culture should be submitted in a sterile cup (rather than on a swab) and without formalin preservative.

Regardless of the culture collection method or specimen being collected, culture for *M tuberculosis* in children has suboptimal yields. Families should understand that AFB smears are not usually positive from specimens from children, that cultures must be incubated for

several weeks before any results are available, and that cultures have less than 50% yield in most situations. Specimens are collected so that if cultures are positive and yield susceptibility data, then the treatment regimen can be optimized. In most cases, the diagnosis of TB in a child is a clinical diagnosis, influenced by the probability of exposure to a person with infectious TB, TST or IGRA results, clinical symptoms and signs, and results of imaging tests. Although none of these elements is diagnostic for TB disease, the experienced TB physician weighs all these factors along with the risk to the child of not treating TB when considering whether to begin treatment. Unless an alternative diagnosis is established, most often, once TB therapy is begun, the course should be completed.

Other laboratory evaluations should be considered based on individual circumstances. Patients who have TB and HIV coinfection, severe TB disease, symptoms or signs of hepatitis, or known underlying liver disease or those who are receiving other hepatotoxic medications should have liver transaminase levels measured.

### Imaging Studies

Any child whose TST or IGRA result is positive or who is suspected of having pulmonary or extrapulmonary TB should have a chest radiograph performed. For the best-quality radiograph, the child should be in full inspiration and should not be rotated. Guidelines suggest obtaining 2-view radiographs on all children when resources permit. If resources are limited, children older than 6 years can be screened with 1-view

chest radiographs. The lateral view is particularly helpful in distinguishing other central shadows from intrathoracic lymph nodes, which are spherical and can often be seen on both views. Ideally the films should be interpreted by a physician or radiologist experienced in pediatric TB. Computed tomography is not indicated in the evaluation of an asymptomatic child with a normal chest radiograph and a positive TST or IGRA result. A computed tomography scan can be helpful when the radiograph is equivocal and when looking for other causes of lung disease is necessary.

Findings on chest radiographs of children with TB are variable. Enlarged intrathoracic lymph nodes and infiltrate are the most common abnormalities. Intrathoracic adenopathy is often seen in children and is reported to be present in up to 85% of children younger than 3 years. Hilar, mediastinal, paratracheal, and subcarinal nodes may be seen and are most often found on the right side. Isolated adenopathy should be considered as possible TB disease. Figure 341-5 shows the radiograph of a child with typical intrathoracic adenopathy caused by TB.

An infiltrate may be seen in any lung field and is seen in multiple lobes in one-fourth of children. Parenchymal disease may be caused by several processes. A larger consolidation may be associated with advancement of the infection—the so-called progressive primary process—or it may be caused by atelectasis or collapse and consolidation that results from lymph node obstruction. Lymph node obstruction can also cause air trapping behind the node with resultant wheezing and hyperinflation. Older children, especially

### BOX 341-5 Gastric Aspirate Procedure for Culture of *Mycobacterium tuberculosis*

- Health care workers present during gastric aspirate procedures of a patient with suspected or confirmed infectious TB disease should wear at least a N-95 disposable respirator.
- Collect all supplies and have everything ready: N-95 respirators, papoose board or sheet, No. 10 French or larger nasogastric or suction tube, 30-mL syringe with appropriate connector for tube; pen; sterile water; specimen cup or laboratory-prepared tube containing bicarbonate for bedside neutralization; requisition and label; helper.
- Child should not take anything by mouth for at least 6 hours before the procedure.
- Immobilize the child with a sheet with or without a papoose board.
- Measure the distance from the nose to the stomach.
- Insert a No. 10 French (or larger) nasogastric tube through the nose into the stomach.
- Puff in the child's face as the tube enters the throat to elicit a swallow reflex.
- Gently aspirate the tube with an appropriately fitted 30- to 60-mL syringe.
- If no significant yield, then advance and withdraw the tube slightly while aspirating.
- If yield is still less than 5 to 10 mL, then place any collected mucus into a container.
- Check tube position by auscultating the stomach while pushing air from the syringe into tube.
- Instill 20 mL of sterile water into the stomach and quickly aspirate again.
- If yield is less than 5 to 10 mL, then roll the child on the side, advance the tube, aspirating continuously to find the pool of mucus in the stomach.
- As tube is withdrawn, continuously aspirate the syringe.
- Place any yield, including any spontaneously vomited emesis, in the specimen container.
- Label the specimen and order AFB smear and culture.
- Promptly transport the specimen to the laboratory for processing (tell the laboratory if the specimen has already been neutralized).

AFB, Acid-fast bacillus; TB, tuberculosis.

From Curry International Tuberculosis Center. Pediatric Tuberculosis: A Guide to the Gastric Aspirate Procedure. Available at: [www.currytbcenter.ucsf.edu/topics-interest/pediatric-tb](http://www.currytbcenter.ucsf.edu/topics-interest/pediatric-tb). Accessed February 3, 2016. Reprinted by permission.

adolescents, may have radiographic findings that are consistent with adult reactivation (postprimary) TB, including upper lobe disease with fibronodular infiltrates, volume loss, hilar retraction, and cavities.

Infection is sometimes spread to other parenchymal locations after erosion of a lymph node with spilling of infectious material (bronchogenic spread). This situation can cause a segmental lesion when the material is

**Figure 341-5** Chest radiograph of a child with enlarged intrathoracic lymph nodes.

limited to 1 bronchus, or it may result in diffuse bronchopneumonia when the organism spreads throughout the lung.

Distribution of *M tuberculosis* through hematogenous dissemination that causes disease to the lung and other organs is termed *disseminated disease*, although the term *miliary disease* was formerly used because of the small, round, millet-like appearance of the diffuse lesions. Figure 341-6 shows the radiograph of an infant with disseminated TB. Primary bacillema occurs during the initial process of the proximal lymph nodes draining into the thoracic duct. The infection may also be disseminated secondarily if a necrotizing lymph node or air space focus erodes into a blood vessel. These disseminated processes do not always appear radiographically in the classic disseminated pattern. Larger, patchy, reticulonodular lesions may be present and difficult to distinguish from other diffuse lung infections.

Pleural effusion and empyema are less common in children with TB compared with adults. Isolated, small, dense nodules with calcification, nonenlarged calcified lymph nodes, and isolated pleural thickening are considered signs of healed *M tuberculosis* infection and are not considered to be TB disease. Peribronchial cuffing or thickening is commonly associated with reactive airway disease and viral infection and, in isolation, is not consistent with TB.

The pediatrician should obtain a chest radiograph 2 months after therapy for TB disease has begun, whenever clinically indicated, and again when therapy has ended. Radiographic abnormalities in children with TB resolve slowly, and enlargement of lymph nodes may persist for a long period. The chest radiograph is not normal in more than one-half of children at the end of therapy. However, these children continue to

**Figure 341-6** Chest radiograph of infant with disseminated tuberculosis.

improve gradually. The radiograph at the completion of therapy should be greatly improved compared with the original radiograph, which will serve as a baseline for monitoring future changes. The chest radiograph need not be repeated for children receiving or completing LTBI treatment unless they develop symptoms compatible with TB disease.

### Treatment of Tuberculosis Disease

In all states, Puerto Rico, and US territories, physicians are legally mandated to report persons suspected of having or confirmed to have TB to the local health department. Reporting is an important public health function because the health department assumes responsibility for collaboration in case management, provides direct observation therapy (DOT), and tests exposed contacts.

Children with TB disease should be managed in a dedicated TB clinic or by the most experienced pediatric TB physician available. In areas where this treatment is not feasible, close and ongoing consultation with an experienced physician should be sought.

Children with clinical or radiographic evidence of TB disease, regardless of the TST or IGRA result, should be evaluated immediately, as outlined in Figure 341-4. Specimens for AFB smear and culture should be collected. TB disease is difficult to diagnose definitively in children because culture confirmation is often lacking or can be delayed for several weeks. Children who have a positive TST or IGRA result, who have known exposure to TB or risk factors for TB exposure, who have radiographic changes consistent with TB, or who have relatively few symptoms compared with their radiographic changes are more likely to have TB as opposed to alternative diagnoses such as community-acquired pneumonia or reactive airway disease.

Table 341-3 shows treatment regimens for TB disease in children. A 4-drug empirical regimen (INH, rifampin, pyrazinamide, and ethambutol) is indicated for most children suspected of having TB disease (most experts would initiate just 3 drugs for children exposed to an adult with drug-susceptible disease). After 2 months of treatment, a repeat chest radiograph should be performed. For children from whom sputum can be obtained, follow-up sputum should be obtained to document culture conversion. If the patient has been adherent to therapy, is clinically well, has an improving or at least stable radiograph, and there is no reason to suspect drug resistance, the regimen can then be changed to 2 drugs (INH and rifampin) to complete a 6-month course. Select children and adolescents may require extension of treatment to a 9-month course. Twice- or thrice-weekly dosing by DOT can be used after the 2-month induction phase of daily treatment if the child is tolerating the regimen well and has shown considerable clinical improvement. The number of doses actually observed should be counted when considering whether a patient has completed therapy. Patients receiving daily doses for the first 2 months will typically receive 40 observed doses (Monday through Friday for approximately 8 weeks) followed by 36 twice-weekly or 54 thrice-weekly doses in the following 18 weeks.

Treatment of INH-mono-resistant TB disease requires at least 6 months of rifampin, pyrazinamide, and ethambutol. Treatment of drug-resistant TB should be performed in consultation with an expert in this area.

The most important element of TB therapy is the actual ingestion of the drugs. Children are difficult to dose with TB drugs, given that the formulations are not particularly child friendly. See dosing suggestions in the previous section on Latent Tuberculosis Infection. The parents and public health staff should be warned that they might have to endure a several-week period of trial and error. Patients should be monitored monthly during therapy. Routine laboratory evaluation need not be performed unless the patient has symptoms of toxicity or underlying liver disease or unless the patient is taking other medications, which might interfere with the TB drugs or cause similar toxicities.

An end-of-therapy chest radiograph should be obtained. Many children do not have a normal radiograph at the end of therapy, but significant improvement is expected.

Corticosteroids have been shown to be beneficial in central nervous system disease, particularly stage 2 and 3 (altered mental status). Some physicians would use steroids for any child with symptomatic TB meningitis. Steroids are also often used for TB pericarditis. Two reports support the use of steroids in children with symptomatic airways compression caused by lymphatic disease. Prednisone is generally used at a dose of 1 to 2 mg/kg/day given for 4 to 8 weeks and then tapered over several weeks.

## CONCLUSION

TB is a focal problem in the United States, disproportionately affecting immigrant and minority populations. TB risk assessments at well-child and other visits have replaced universal screening of children by TST. Only children who have a new risk for TB exposure since the last TST or IGRA or who have features suggestive of TB disease should undergo the TST or IGRA. All children diagnosed as having LTBI should be treated and closely monitored for adherence and toxicity. Providers should develop or modify systems to remove barriers to completion of therapy, including walk-in nurse visits, minimal paperwork, easy chart forms, and incentives. Many children with TB in the United States are asymptomatic at the time of diagnosis. TB disease in children is diagnosed clinically and radiographically, often without culture confirmation. Experienced TB physicians are best qualified to manage TB disease, but ongoing consultation should be sought when local resources are limited.

Prevention of TB includes identification of children at risk for exposure to TB, aggressive evaluation of children exposed to potentially contagious adolescents and adults with TB (young children are generally not contagious), treatment of LTBI, and prompt treatment of contagious TB patients.

### WHEN TO REFER

- All patients suspected of having TB disease should be reported to the local health department according to state statute (eg, within 1 working day).
- In many jurisdictions, young children with LTBI should be reported to the local health department, according to local regulations.

- Ideally, an experienced pediatric TB physician should manage children with TB disease. If local resources are not available, then close and ongoing consultation with a pediatric TB expert should be established.
- Any patient whom you suspect has multidrug-resistant TB should be treated by a pediatric TB expert or with ongoing and close consultation

### WHEN TO ADMIT

- Children should be admitted to the hospital for culture collection if local resources are not available for outpatient culture collection.
- Few children require admission to the hospital based on clinical severity of TB disease. Patients

with increased work of breathing, meningitis, or complicating simultaneous conditions or patients who require diagnostic evaluation should be admitted.

### Chapter 342

## TURNER SYNDROME AND NOONAN SYNDROME

Jonathan C. Howell, MD, PhD; Philippe Backeljauw, MD

### TURNER SYNDROME

#### Definition and Etiology

Turner syndrome (TS) describes a phenotype of girls with short stature, gonadal failure, and varying degrees of skeletal, cardiovascular, renal, endocrine, lymphatic, and neurodevelopmental abnormalities; it is genetically characterized by an abnormal or missing X chromosome. It was first described as a syndrome of sexual infantilism, cubitus valgus, and webbing of the neck by Henry Turner in 1938. All individuals with TS have a female phenotype; males are not given this diagnosis. Turner syndrome is caused by loss of all or part of one of the X chromosomes. Some children have structural abnormalities of the X chromosome, such as deletions of a portion of the short arm, a ring X chromosome, or an X isochromosome. These individuals can be clinically indistinguishable from the classic (45,X) TS patient. Some female children with TS (5% to 6%) have karyotypes including Y chromosome material, such as in 45,X/46,XY mosaicism.

#### Epidemiology and Risk Factors

Turner syndrome occurs in approximately 1 in 2,000 live female births. With about 2 million live female births in the United States annually, this translates to 800 females born with TS every year. Approximately 3% of all females conceived have TS, but nearly 99% of all TS conceptions do not survive beyond 28 weeks of gestation. Risk factors for TS include faulty chromosome distribution, such as nondisjunction during paternal meiosis, or postfertilization mitotic errors leading to TS mosaicism (eg, 45,X/46,XX). In rare cases, familial TS is transmitted by a carrier of a balanced translocation.

#### Diagnosis

##### Signs and Symptoms

Owing to the haploinsufficiency of several genes encoded on the X chromosome, the presentation can be heterogeneous. See Figure 342-1 and Table 342-1 for the characteristic features of TS.

#### Differential Diagnosis

The differential diagnosis of TS must include Noonan syndrome (NS), and a karyotype will reveal no sex chromosome abnormalities in NS patients. Additionally, NS is often associated with right-sided heart abnormalities, whereas TS heart defects are typically left-sided. Additionally, in the differential diagnosis for TS is any disorder causing growth failure or short stature in females: hypothyroidism, growth hormone deficiency, skeletal dysplasia, short stature associated with chronic illness, and normal short stature variants. Although primary ovarian failure is quite common in girls

**Figure 342-1** Photo of patient with Turner syndrome. The arrows point to some of the classical features: (A) short webbed neck; (B) cubitus valgus; (C) lymphedema. (From Gawlik A, Malecka-Tendera E. Hormonal therapy in a patient with a delayed diagnosis of Turner syndrome. *Nat Clinical Pract Endocrinol & Metab.* 2008;4(3):173–177. Reprinted with permission from Nature Publishing Group.)

with TS, those presenting with delayed puberty and amenorrhea must be distinguished from those with any other cause of ovarian failure (long-term survivors of childhood neoplasia, autoimmune ovarian disease).

**Diagnostic Approach**

For the diagnosis of TS, karyotyping with a minimum of 30 cells in metaphase will identify at least 10% mosaicism with 95% confidence. Testing for the presence of Y chromosome material should be done by fluorescent in situ hybridization in any child with chromosome material of unknown origin. The diagnosis of TS is often made late (late childhood and beyond), and cytogenetic analysis should be considered for all females with unexplained short stature, pubertal delay, or any constellation of other clinical findings of TS. Turner syndrome is increasingly diagnosed prenatally through amniocentesis or chorionic villus sampling. If a karyotype was obtained in utero, it should be repeated following birth. Features suggestive of TS found on fetal ultrasonography include polyhydramnios, edema, and increased nuchal fluid. Fetal echocardiography is indicated at 18 to 20 weeks of gestation if TS is suspected.

Table 342-1 Characteristic Features of Turner Syndrome	
AREA	FEATURE
Cardiovascular	Coarctation of the aorta Bicuspid aortic valve Aortic root dilation/dissection Hypertension
Craniofacial	Epicanthal folds Excess nuchal skin Webbed neck Low posterior hairline
Dermatologic	Pigmented nevi
Endocrine	Hypothyroidism
Genitourinary	Gonadal dysgenesis—leads to delayed/absent puberty Streak ovaries (most infertile) Renal malformations (horseshoe kidneys most common)
Growth	Short stature
Musculoskeletal	Lymphedema of hands and feet at birth Deep-set hyperconvex nails Short fourth metacarpals Cubitus valgus Broad chest with wide-spaced nipples Scoliosis
Neurodevelopment	Learning difficulties (typically normal intelligence)
Ophthalmologic	Strabismus
Otolaryngologic	Hearing loss

From Lyons MJ. Specific genetic conditions. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013.

**Laboratory Evaluation and Imaging**

Anticipatory monitoring is highly recommended during the lifetime of children with TS (see Table 342-2 for a screening schedule). Females with TS are encouraged to regularly see an endocrinologist to address their growth, pubertal delay, and bone health. Further specialty involvement comes from a cardiologist if cardiac anomalies are present, a nephrologist if renal disease is apparent on ultrasonography, and an ear, nose, and throat specialist with an audiologist to address recurrent otitis and hearing loss. If learning, processing, and attention difficulties are suspected, evaluation by a developmental pediatrician, a psychologist, or other mental health providers is recommended.

**Management**  
**Growth and Endocrine Issues**

Short stature in TS is related to short stature homeobox (*SHOX*) gene deficiency resulting from the loss of all or part of the X chromosome. Growth charts are available for use in the clinical setting (Figure 342-2). Infants often have some degree of intrauterine growth restriction, and postnatal growth lags behind that of other children. Feeding difficulties can negatively affect nutrition and weight gain. There is delayed

**Table 342-2** Screening and Monitoring for Turner Syndrome

AGE	SCREENING AT DIAGNOSIS	ONGOING MONITORING
All patients	Cardiology consultation (Figure 342-2) Renal ultrasonography Audiology evaluation Examination for scoliosis/kyphosis Discussion of aspects of TS Support group referral Evaluation of progress of growth and pubertal development	Cardiology follow-up and evaluation as indicated Annual blood pressure check Re-evaluation by ENT/audiology physician every 1–5 years Growth evaluation
Age 0–4 years	Hip examination for congenital hip dislocation Pediatric ophthalmology examination (age >1 year)	Social skills evaluation at age 4–5 years
Age 4–10 years	Thyroid function testing ( $T_4$ , TSH) Celiac screen (tTG Ab) Educational/psychosocial assessment Orthodontic evaluation (age >7 years)	Liver/thyroid screening yearly Celiac screen every 2–5 years Yearly education/social progress evaluation Dental/orthodontic evaluation as needed
Age >10 years	Thyroid function testing ( $T_4$ , TSH) Celiac screen (tTG Ab) Educational/psychosocial assessment Ovarian function evaluation Begin estrogen replacement when appropriate Liver function testing, fasting blood glucose, CBC, renal function testing Bone mineral density (age >18 years)	Fasting lipids/blood glucose yearly Liver/thyroid screening yearly Celiac screen if clinically indicated Evaluation of pubertal development and psychosocial development at age-appropriate times

Ab, antibody; CBC, complete blood count; ENT, ear, nose, and throat;  $T_4$ , thyroxine; TS, Turner syndrome; TSH, thyroid-stimulating hormone; tTG, tissue transglutaminase.

Adapted from Loscalzo ML. Turner Syndrome. *Pediatr Rev.* 2008;29(7):219–222; and Bondy CA. Care of girls and women with Turner syndrome: a guideline of the Turner Syndrome Study Group. *J Clin Endocrinol Metab.* 2007;92(1):10–25.

childhood growth and lack of a pubertal growth spurt in most girls with TS. Treatment with recombinant human growth hormone (GH) has been approved for TS patients since 1996, and GH therapy should be considered as soon as growth failure is confirmed.

In a randomized, controlled trial of GH in girls with TS initiated before the age of 4 years, significant improvement in height standard deviation (SD) scores compared with matched controls was shown, and GH restored height into the normal range in 93% of patients by the age of 6 years. Additional studies have shown variable increases in final adult height relative to pretreatment projected height, depending on the type of study considered (range between 5.1 and 17.2 cm, with a mean of 7.0 cm). Children with earlier age at GH initiation and longer duration of GH therapy demonstrated the most benefit. Other advantages of early GH treatment initiation include improvement in peer group integration and the ability to provide age-appropriate estrogen replacement.

In those with a relatively late diagnosis of TS (ie, about 8 to 10 years of age), oxandrolone, a nonaromatizable anabolic steroid with weak androgen effect, given for up to 4 years, may be considered as adjuvant therapy for growth promotion. Although it results in height gain improvement in many girls, this addition of oxandrolone to GH therapy may yield only modest augmentation in height gain in some children. It is also often accompanied by a deceleration in breast development.

Individuals with TS are prone to develop autoimmune conditions. Autoantibodies are present in nearly

60% of female TS patients, and 18% of those have more than 1 organ targeted. Annual screening of thyroid function is recommended. Treatment of hypothyroidism because of autoimmune thyroiditis is usually at typical doses used to treat hypothyroidism, and regular follow-up with an endocrinologist is required. The incidence of celiac disease among TS patients is 6%. Screening for tissue transglutaminase should occur by age 4 and every 2 to 5 years thereafter.

### Cardiovascular Issues

If cardiovascular anomalies are found on initial screening, individuals with TS should have further evaluation by a pediatric cardiologist (Figure 342-3). Hypertension warrants periodic evaluation for aortic dilation, increasingly being done by cardiac magnetic resonance imaging. Obesity is a common feature of TS that can complicate treatment for hypertension and result in negative effects on cardiac health. Baseline measurement of fasting glucose, insulin, lipids, and liver enzymes are helpful from age 10 years on, with follow-up testing at 1- to 2-year intervals and as needed.

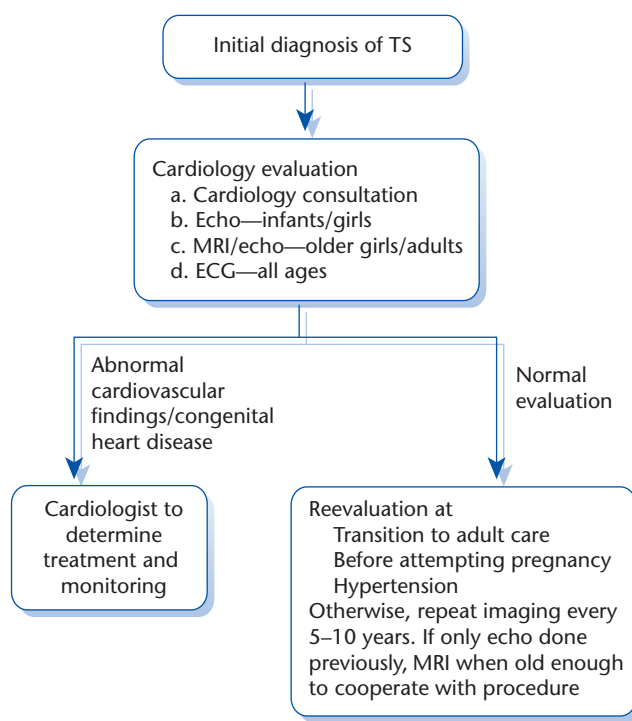

### Renal and Genitourinary Issues

Renal malformations in TS children are relatively common, although not always with clinical implication. Horseshoe kidney, ectopy, and malrotation are typical structural abnormalities. Children with renal defects are more likely to have hypertension. A renal ultrasound should be obtained at diagnosis, and consultation by a pediatric nephrologist is recommended if the findings are abnormal.

**Figure 342-2** Turner syndrome-specific stature chart overlaid with percentiles of normal children aged 2–19 years. (Data originally adapted from Lyon AJ, Preece MA, Grant DB. Growth curve for girls with Turner syndrome. Arch Dis Childhood. 1985;60(10):932–935.)

**Figure 342-3** Recommendations for cardiac evaluation of TS patients. ECG, electrocardiogram; MRI, magnetic resonance imaging; TS, Turner syndrome. (Adapted from Loscalzo ML. Turner syndrome. *Pediatr Rev.* 2008;29(7):219-227.)

### Pubertal Delay and Hypogonadism

Because of gonadal dysfunction, up to 30% of TS patients have some degree of spontaneous puberty. Follicle-stimulating hormone (FSH) concentrations are increased in the first 1 to 2 years of life, followed by a gradual decline in mid to late childhood. In females with mosaic TS, FSH can be indistinguishable from that of healthy females. Estrogen therapy is used to induce the development of the secondary sexual characteristics, followed by progestin cycling. The exact timing of pubertal induction is still the subject of ongoing study. Current recommendations are to consider treatment between the ages of 12 and 13 years if no spontaneous puberty has occurred. Timely treatment with estrogen can promote bone health and improve psychological outcomes of adolescent girls. Many forms of estrogen are available, including oral, transdermal, and injectable. Physiologic low-dose replacement is preferable, with a gradual increase in dosing every 4-6 months, and this is best achieved with transdermally applied estradiol preparations. Progesterone is withheld until 18 to 24 months after estrogen initiation, or when breakthrough menstruation occurs.

### Vision and Hearing

Individuals with TS can have a variety of eye problems because of structural eye abnormalities (downward sloping palpebral fissures, ptosis, and epicanthal folds). Strabismus and hyperopia have been reported in up to 30% of patients. Initial ophthalmologic evaluation is recommended between 1 and 2 years of life.

The pediatrician should maintain a high level of suspicion for otitis media. Light otoscopy and pneumatic tympanometry are useful throughout childhood. Current recommendations also include ENT and audiology evaluation every 1 to 5 years. If hearing loss or chronic ear infections are present, yearly audiology examinations should take place, and referral to an audiologist is recommended. For those without documented hearing loss or chronic otitis, similar examinations can take place every 2 to 3 years.

### Neurologic, Cognitive, and Behavior Issues

For most TS children, intelligence is typical. However, it is common to score lower on assessments of nonverbal learning and demonstrate reduced speed in mental processing, or to have deficits in executive function. Careful attention should be paid if school performance begins to decline. Families should be encouraged to request educational accommodations, such as extra time to complete homework or examinations. Poor social skills and challenges in executive functioning can often lead to and be exacerbated by social isolation. Questionnaires provided to adolescents with TS have shed light on social anxieties related to delayed puberty and questions surrounding fertility. It is important to be honest when discussing fertility with patients and their families. Alternative means of motherhood, such as adoption, should be explored. Psychosexual and vocational counseling may require input from psychologists, educators, and school counselors.

### Orthodontics and Skin Issues

Dental malocclusion, articulation defects, micrognathia, and crowded teeth are common in TS children because of a narrow maxilla and small mandible. Orthodontic evaluation is begun by 7 years of age.

Generalized lymphedema with excessive nuchal skin, easy bruising, and hyperpigmentation can be seen in individuals with TS. The risk for melanoma is not increased over the general population, but TS children often develop multiple nevi. They are also more likely to have keloid scarring. Lymphatic accumulation in TS can be associated with fetal hydrops, pleural effusions, lymphangiectasis, and anomalous lymphatic vessels. Although the neonatal lymphedema improves over time, the management of persistent lymphedema can be difficult, and follow-up with a specialized center is recommended.

## NOONAN SYNDROME

### Definition and Etiology

Although children with NS can have a similar phenotype to TS, with short stature, neck webbing, and gonadal failure (in males), the etiology is completely different, and individuals with NS have normal 46,XX or 46,XY karyotypes. Slightly more than half of children with NS have a dominant-negative mutation in the *PTPN11* gene, which encodes the nonreceptor protein tyrosine phosphatase signaling molecule, SHP-2. This mutation leads to disruption of intracellular signaling of several growth factors, cytokines, and hormones. Other less common mutations in genes

**Figure 342-4** Broad neck, wide-spaced nipples, and facial features in a female with Noonan syndrome. (From Lyons MJ. *Specific genetic conditions*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013:175–234.)

encoding signaling molecules have also been identified (*KRAS*, *RAF1*, *SOS1*, *BRAF*, *SHOC2*, *NRAS*, and *MEK1*). Characterization of the NS phenotype occurred in the late 1960s by Jacqueline Noonan. In addition to distinct facial features, children with NS often have cardiac, endocrine, skeletal, neurologic, and hematologic abnormalities.

**Epidemiology and Risk Factors**

The incidence of NS is reportedly between 1 in 1,000 and 1 in 2,500 live births. Transmission of NS is thought to be autosomal dominant, with many cases arising spontaneously. Moreover, a wide variability in the presentation of NS is indicative that the phenotypic features of NS can be caused by a variety of molecular etiologies.

**Diagnosis**

**Signs and Symptoms**

The variable genetic background of NS leads to a wide range of features. See Figure 342-4 and Table 342-3.

**Differential Diagnosis**

Although TS should be considered in the differential diagnosis for females with NS, several other syndromes have overlapping phenotypes with NS. These include Cardio-facio-cutaneous syndrome, Costello syndrome, Neurofibromatosis type 1, and LEOPARD syndrome (multiple lentigines, electrocardiogram conduction abnormalities, ocular hypertelorism, pulmonic stenosis,

Table 342-3	Characteristic Features of Noonan Syndrome
AREA	FEATURE
Cardiovascular	Pulmonic stenosis Hypertrophic cardiomyopathy Lymphatic abnormalities
Craniofacial	Low-set ears Posteriorly rotated ears Fleshy helices Hypertelorism Downward-slanting palpebral fissures Epicanthal folds Ptosis Thick eyelids Broad, webbed neck
Genitourinary	Cryptorchidism in males Renal abnormalities
Growth	Short stature
Hematology	Coagulation defects
Musculoskeletal	Superior pectus carinatum with inferior pectus excavatum Low-set nipples
Neurodevelopment	Developmental delay Mild intellectual disability (may be present in one-third of cases)
Ophthalmologic	Strabismus
Otolaryngologic	Hearing loss

From Lyons MJ. *Specific genetic conditions*. In: Saul RA, ed. *Medical Genetics in Pediatric Practice*. Elk Grove Village, IL: American Academy of Pediatrics; 2013.

abnormal genitalia, retardation of growth, and deafness). Syndromes with distinct facial dysmorphology, cardiac defects, and short stature (Williams and Aarskog syndromes) may be difficult to differentiate from NS.

**Diagnostic Approach**

DNA sequencing, liquid chromatography, and oligonucleotide microarray testing are available to detect the gene mutations associated with NS. If NS is clinically suspected, initial screening for a *PTPN11* mutation is recommended. When *PTPN11* mutations are absent, other mutations can be investigated (Table 342-4). The availability of the Noonan Spectrum Panel performed by next-generation gene sequencing allows for a comprehensive analysis of potentially pathologic variants that may offer definitive diagnosis. However, the lack of a detectable genetic mutation does not rule out a diagnosis of NS in patients for whom there is a strong clinical suspicion, and, in total, the frequency of gene mutations among children with NS is only approximately 60%. Prenatal diagnosis can be achieved through amniocentesis or chorionic villus sampling, and findings such as polyhydramnios, edema, and increased nuchal fluid on fetal ultrasonography, can suggest NS. If NS is suspected during prenatal evaluation, fetal echocardiography is also indicated. Several clinically based scoring systems are in place to help diagnose NS (see Table 342-5).

### Laboratory Evaluation and Imaging

A similar multidisciplinary approach has been advocated for NS as previously described for TS. A pediatric genetics consultation and follow-up are recommended at diagnosis. Because negative genetic testing cannot always rule out an NS diagnosis, a decision about whether to obtain genetic testing relies in part on family preference and the presence or absence of additional features associated with NS (see Table 342-4).

### Management

Management and interval comorbidity screening recommendations are summarized in Table 342-6.

### Growth and Endocrine Issues

The GH-secretory dynamics in NS reflect the existing genetic heterogeneity, and both GH sufficiency and deficiency have been reported. Insulin-like growth factor-I is often lower in *PTPN11* mutation-positive NS patients, which may point to some degree of GH resistance when associated with normal GH secretion. Although birth length is typically preserved, birth weight is often low, and consultation by a gastroenterologist should be obtained in children

who have failure to thrive. Growth spurts for both boys and girls can be delayed because of delayed puberty, and mean NS adult height only reaches the lower limits of normal late in the second decade of life. Recent data suggest that height standard deviation (SD) scores and growth kinetics can vary depending on the exact genetic mutation encountered in the RAS/MAPK pathway. Specific length, stature, weight, and growth velocity charts for NS are available for clinical use (Figure 342-5).

Growth hormone therapy has been approved for use in NS children and should be initiated in consultation with a pediatric endocrinologist when growth failure is evident. Although most studies to date involve small numbers of children, data on adult height achieved with GH therapy suggest there is significant improvement in height SD scores and mean overall height gain (between 9.5 and 13 cm for boys and 9.0 and 9.8 cm for girls). Furthermore, as in TS, earlier treatment and longer duration seem to have the most effect. Children with *PTPN11* mutations may respond less favorably to GH therapy than those without such mutations.

### Cardiovascular Issues

Cardiovascular defects are common in NS and typically involve right-sided malformations. In severe pulmonary valve dysplasia (a subset of pulmonary valve stenosis), a valvectomy or pulmonary homograft is required in childhood. Less severe forms of stenosis can be treated with balloon angioplasty. Hypertrophic obstructive cardiomyopathy can resolve spontaneously in some NS children, or become rapidly progressive. Management includes beta blocker medications and surgical myomectomy to reduce outflow obstruction. Regardless of ultimate cardiac diagnosis, lifetime follow-up by a cardiologist is needed.

### Renal and Genitourinary Issues

Renal anomalies have been reported in 10% to 11% of children with NS and include solitary kidney, renal pelvic dilation, and duplicated collecting system; as in TS, they often are clinically insignificant. Consultation by a pediatric nephrologist is helpful if hypertension is noted. Fertility does not seem to be affected in females with NS. In males, if cryptorchidism is present, prompt

evaluation by a urologist and orchiopexy before 1 year of age are recommended.

### Pubertal Delay/Hypogonadism

Puberty is often delayed in both boys and girls with NS and is accompanied by a decreased growth spurt. Mean age in boys for onset of puberty is between 13.5 and 14.5 years, and in girls, it is between 13 and 14 years. In some instances, puberty may then progress with rapid tempo (<2 years). Induction of puberty with appropriate sex hormone replacement can be accomplished in boys at 14 years of age and girls at 13 years.

### Vision and Hearing

Similar to TS patients, NS children can have frequent otitis media. Examination, not only with light otoscopy but also with pneumatic tympanometry, is useful until at least 7 years of age. If hearing loss is identified or ear infections persist, yearly hearing examinations and referral to an audiologist are recommended. For those without documented hearing loss or chronic otitis, screening audiology is done every 2 to 3 years.

### Neurologic, Cognitive, and Behavior Issues

The neurologic and behavioral aspects of NS are less well understood and quite variable. Learning disabilities, peripheral neuropathy, and seizures are all increased in NS children compared with nonsyndromic children. Although brain structural malformations are relatively uncommon, Arnold-Chiari type I malformations and hydrocephalus are known to occur at low frequencies. A generalized motor delay is present in most. Body image problems and poor self-esteem, depression, and feelings of social inadequacy have all been noted in adolescents and adults with NS. Psychiatric or psychological intervention is recommended for NS children who have poor coping skills, self-injurious behavior, or severe attention deficit/hyperactivity disorder.

### Hematologic, Orthodontic, and Skin Issues

Individuals with NS are at higher risk than the general population for bleeding disorders, and a number of coagulation-factor anomalies have been described: thrombocytopenia, platelet dysfunction, and deficiencies in factors VIII, XI, or XII. Evaluation by a

**Table 342-6** Screening and Monitoring for Noonan Syndrome

CLINICAL SPECIALTY ISSUE	RECOMMENDATIONS
Cardiovascular	Evaluation by cardiologist at time of diagnosis, including echocardiogram and electrocardiogram Regular follow-up if defect present Interval follow-up every 5 years if no defect present
Growth and endocrine	Weight and height measurements regularly by primary physician Evaluation by an endocrinologist if growth deceleration, height $\leq 2$ SD, or delayed puberty Thyroid testing if goiter present
Renal and genitourinary	Renal ultrasonography at time of diagnosis Consider antibiotic prophylaxis with hydronephrosis or recurrent urinary tract infection Orchiopexy performed by age of 1 year if cryptorchidism present
Gastrointestinal	Evaluation by gastroenterologist for feeding difficulties or persistent vomiting
Hematology	Screening CBC with differential, PT, and aPTT at diagnosis and after 6–12 months of age If bleeding, first obtain CBC, PT, and aPTT; then evaluate specific clotting factor activity in consult with hematologist Preoperative evaluation for all surgeries by hematologist
Cognitive and behavioral	Developmental screen annually Complete neuropsychiatric testing if abnormal Evaluations by physical therapist, occupational therapist, and speech therapist if delayed, with earliest intervention possible Individual education plans updated yearly with schools Evaluation by neurologist if seizures suspected Brain and upper spine MRI with any neurologic problem Consider MRI angiogram if sudden focal findings
Eye and ear	Detailed eye examination at diagnosis Eye reevaluation as indicated if problems or at least every 2 years thereafter Hearing testing in infancy and/or at diagnosis with regular testing in childhood
Orthopedic	Annual examination of chest and back, radiography if abnormal
Orthodontic	Dental referral between 1 and 2 years of age Careful oral examination at each visit
Lymphatic	Referral to specialty lymphedema clinic if possible For more information, contact National Lymphedema Network ( <a href="http://www.lymphnet.org">www.lymphnet.org</a> )

aPTT, activated partial thromboplastin time; CBC, complete blood count; MRI, magnetic resonance imaging; PT, prothrombin time; SD, standard deviation.

hematologist is recommended if easy bruising, epistaxis, or menorrhagia is present.

Dental malocclusion, articulation defects, micrognathia, and crowded teeth are all features of NS. Orthodontic evaluation is recommended by 7 years of age.

Lymphedema, excessive nuchal skin, easy bruising, and hyperpigmentation can occur in NS. Lymphatic accumulation in NS can involve fetal hydrops, pleural effusion, lymphangiectasia, and anomalous lymphatic vessels. Management of these can be difficult, and follow-up with a lymphedema center is helpful.

## CLINICAL SIMILARITIES AND TRANSITION TO THE ADULT CLINIC

Although there is some overlap in the clinical features of TS and NS, each represents a distinct diagnosis with a specific genetic etiology (see Table 342-7). Because of the varied manifestations affecting multiple organ systems in both syndromes, children are typically followed by primary care physicians in conjunction with several subspecialty physicians.

Recent attention has been paid to the lack of coordinated transition of TS and NS children from pediatric to adult care physicians, especially because multiple subspecialists are involved from an early age. It is important for the primary care pediatrician to educate young adults with TS or NS about key potential medical and psychosocial issues and empower them to proactively pursue care as they mature. Suggestions include providing children and their families with a medical “passport” documenting medical and surgical history, ongoing medications, advised annual or biannual testing, target weight and blood pressure, and data on prior cardiac evaluation and recommendations. This should be done in succinct and secular language. The use of a transition coordinator to facilitate movement of data and appointments to adult clinics has been shown to be highly effective in some

countries. Furthermore, use of social media, telephone calls, and interactive Web sites can make the transition process more attractive for these children, who are often in the midst of many life changes. For young adults with NS, especially, it is appropriate to undergo genetic counseling given the autosomal dominant inheritance pattern. Because the spectrum of the NS phenotype varies broadly, it may be worthwhile to screen the parents of children with NS for genetic mutations to assess the risk for recurrence.

## Chapter 343

## UMBILICAL ANOMALIES

Robert W. Marion, MD; Joy Samanich, MD

*"[The umbilicus] is all that remains of the stem that bound us to the parental stalk. It is a reminder that we have been plucked and must sooner or later die. It might be said that when the stem is severed, we cease to live in any true sense. We may be ornamental like roses or useful like cabbages but only for a little while. Our dissolution has begun."*

—THOMAS STEPHEN CULLEN, 1916

Despite its essential role in the survival of the fetus during prenatal life, the umbilicus, the external vestige of the umbilical cord, is frequently ignored or overlooked by the pediatric primary care physician. However, aberrations in either the formation or the position of this structure can offer helpful clues to underlying disease in the young child. Major congenital anomalies of the ventral abdominal wall, such as omphalocele, gastroschisis, and exstrophy of the bladder and cloaca, are described in detail elsewhere. This chapter deals with minor anomalies in configuration, placement, and formation of the umbilicus. In addition to the conditions described here, the umbilicus can be the site of both tumors (either vascular or teratomatous neoplasms) and infections (omphalitis).

To understand the causes and significance of anomalies of the umbilicus, a review of some basic fundamentals of the embryologic development of the umbilical cord is necessary.

### EMBRYOLOGIC DEVELOPMENT OF THE UMBILICAL CORD

Appearing within the first 6 weeks of gestation, the umbilical cord is derived from the fusion of 3 separate embryonic structures: (1) the primitive or primary yolk sac, which contains the allantois and a portion of the vitelline duct, transient structures that ultimately form

the central portion of the embryonic gut, the urinary bladder, the urachus, and the umbilical blood vessels (usually 2 arteries and 1 vein); (2) the secondary yolk sac, composed of the remainder of the vitelline duct; and (3) the mesenchyme of the connecting body stalk of the embryo, the tissue that produces Wharton jelly, which is the packing substance that holds the cord together. After fusion is complete, these unified structures become covered by the amnion and are ultimately surrounded by amniotic fluid.

Many of these embryonic structures that form the umbilical cord are present for only brief periods during embryogenesis. After the seventh week of gestation, the vitelline duct regresses and is ultimately completely resorbed. Similarly the allantois, which is contiguous with the urinary bladder, degenerates, forming a fibrous cord called the *urachus*, which connects the apex of the bladder with the umbilicus. Anomalies may result when these structures fail to undergo normal regression, causing them to persist into postnatal life.

### ANOMALIES

#### Abnormalities of Position and Morphology

Anatomically, the level of the umbilicus is usually at the top of the iliac crest ventral to the third or fourth lumbar vertebra. Variations in the position of the umbilicus can result from abnormalities in the way in which the abdominal wall itself has formed and, as such, may be a clue to the diagnosis of specific dysmorphic syndromes. For example, as described in Table 343-1, the umbilicus has been noted to be low set in achondroplasia (in which disproportionate growth of the trunk accounts for the aberration in position), in bladder and cloacal exstrophy, and in association with various anomalies of the urinary tract. Higher than normal placement of the umbilicus occurs in Robinow syndrome, a condition also known as *fetal face syndrome* because of the striking ocular hypertelorism and macrocephaly that occurs in affected individuals.

Variations in the appearance of the umbilicus, as well as abnormal location, can suggest the presence of a syndrome. In Aarskog-Scott syndrome, also known as *faciogenital dysplasia*, a disorder that combines abnormalities of the face (ocular hypertelorism, small nose with anteversion of the nares, minor anomalies of the ears), digits (mild soft-tissue webbing with clinobrachydactyly of the fifth fingers), and genitalia (*shawl*

Table 343-1

Conditions Associated With Abnormalities in Position or Morphology of the Umbilicus

DISORDER	ABNORMALITY IN POSITION	ABNORMALITY IN MORPHOLOGY
Aarskog-Scott syndrome	—	Prominent, protruding, pouting
Achondroplasia	Low placement	—
Bladder exstrophy	Low placement	—
Cloacal exstrophy	Low placement	—
Cornelia de Lange syndrome	—	Hypoplasia
Rieger syndrome	—	Prominent, broad, redundant periumbilical skin
Robinow syndrome	High placement	Broad, scar is poorly epithelialized

scrotum, cryptorchidism), the umbilicus is prominent and appears pouting and protuberant. In Robinow syndrome, previously described, the umbilical scar is broad and poorly epithelized. Hypoplasia of the umbilicus occurs in Cornelia de Lange syndrome, a disorder combining growth and developmental retardation with a characteristic facial appearance and multiple congenital anomalies. Finally, in Rieger syndrome, which combines iris dysplasia and other ophthalmologic malformations with hypodontia (absence of the upper incisors), failure of involution of the periumbilical skin occurs, leading to a protruding umbilicus.

### Embryonic Umbilical Remnants

As previously noted, the umbilical cord is formed of the vitelline duct, which connects the yolk sac to the midgut; the allantois, which ultimately degenerates into the urachus, a structure that forms a connection between the apex of the urinary bladder and the umbilicus; and the umbilical blood vessels. Persistence of these structures can lead to the presence of anomalies within the newborn; unfortunately, there are usually no external indicators of the persistence of these structures, making diagnosis impossible before symptoms and signs occur.

Failure of the closure and total regression of the vitelline duct by the seventh week of gestation may lead to the presence of Meckel diverticulum (an outpouching of the gut without attachment to the anterior abdominal wall), a vitelline cyst or enterocystoma (a connection between the midgut and umbilicus without communication with either structure), an enteric or vitelline fistula (formed from a communicating connection between the midgut and the umbilicus), or a urachal sinus, cyst, or fistula (resulting from a connection between the bladder and the urachus) (Figure 343-1). In a child, the presence of these anomalies may be signaled by the presence of signs of infection and of a lower midline abdominal mass (caused by infection of a vitelline cyst); the discharge of feces and urine, which can lead to an erosive dermatitis (from enteric and urachal fistulas); and urinary tract infections (also resulting from urachal fistulas). Furthermore, the persistence of a fibrous band of tissue attached to the gut, the result of incomplete involution, may serve as the lead point for a volvulus or the cause of intestinal obstruction.

Of all these anomalies, Meckel diverticula clearly are the most common. Present in 2.5% of newborns in the United States, they are a well-known cause of clandestine lower intestinal bleeding in children and adults. The bleeding results from the presence of ectopic gastric mucosa within the diverticulum, which is prone to ulceration and hemorrhage. Additionally, given that these diverticula, which can occur anywhere from the ileocecal valve to a point 3 feet or more proximal to the valve, resemble a supernumerary vermiform appendix, their presence may be signaled by symptoms and signs of acute appendicitis.

Embryonic umbilical remnants that are lined with gastric mucosa can be detected by gastrointestinal radionuclide scans using technetium-99m ( $^{99m}\text{Tc}$ ) pertechnetate. Sonography or computed tomography is helpful in delineating vitelline cysts that, after onset of

**Figure 343-1** Embryonic umbilical remnants. **A**, Meckel diverticulum. **B**, Enterocystoma. **C**, Enteric (vitelline) fistula. **D**, Urachal sinus. **E**, Urachal cyst. **F**, Urachal fistula.

infection, exhibit as abdominal masses. The presence of a urachal fistula can best be documented by noting the presence of methylene blue dye in the urine after the dye has been instilled at the umbilicus. Surgical excision and repair is the treatment of all internal umbilical cord remnants that are symptomatic.

### Vascular Abnormalities of the Umbilical Cord

Derived from the primitive or primary yolk sac, the blood vessels are the most important structures present in the umbilical cord. Although usually consisting of 2 arteries and 1 vein, variations on this pattern are well known, occurring in 0.7% of all births. By far the most common variation is the presence of only 2 vessels in the cord, consisting of 1 vein and 1 artery. In 25% to 50% of cases, this arrangement is associated with various additional anomalies, including malformations of the central nervous system, genitourinary tract, spine, and extremities.

The pattern of anomalies seen in infants with aberrant cord vessels often depends on which vessels are present and which are missing. Blackburn and Cooley describe 3 separate patterns. In the first pattern, the single umbilical artery is of allantoic origin; this pattern is associated with growth restriction, anomalies of the central nervous system such as anencephaly and spina bifida, and abnormalities of the lower genitourinary tract. In the second pattern, the single artery is of vitelline origin; associated anomalies include sirenomelia, sacral agenesis, reduction defects of the lower extremities, anal atresia (features of the VACTERL [vertebral, anal atresia, cardiac, trachea, esophageal, renal, and limb defects] association), and trisomy 18. Infants with the third pattern have cords that have 3 vessels, including a single umbilical artery (of either allantoic or vitelline origin), a left umbilical vein, and

a persistent and aberrant right umbilical vein; such a pattern has been described in some children with Noonan syndrome and 47,XXY karyotype.

### Umbilical Hernia

The predisposition to develop an umbilical hernia occurs during the second trimester after the midgut, which has until then been developing extra-abdominally, returns to the abdominal cavity. Failure to form the normal fascial reinforcements that keep the midgut in place leads to a weakness in the abdominal wall.

Umbilical hernias are so common that they should be considered a variation of normal. The incidence varies with race and age. Evans found that at 6 weeks of age, 32% of black infants had umbilical hernias, whereas only 4% of white babies did. At 1 year, the prevalence decreased to 12% and 2%, respectively. Low-birth-weight babies are also at markedly increased risk. No gender predilection has been noted: boys and girls are equally affected.

In most affected individuals, umbilical hernias are associated with no medical sequelae. One study revealed that incarceration, strangulation, rupture, or skin breakdown occurred in less than 5% of 590 children. Other studies have revealed even lower rates of complication. Furthermore, in most cases, the hernia will close spontaneously without any medical intervention. Thus, the major indication for surgical treatment of the condition is cosmetic. As such, surgery should only be considered in carefully selected individuals.

Although most umbilical hernias occur as isolated findings in otherwise healthy children, they can also be associated with a variety of known conditions, many of which feature increased abdominal girth or hypotonia. As shown in Box 343-1, these conditions include the common autosomal trisomies, the mucopolysaccharidoses and other inborn errors of metabolism that are associated with organomegaly, and various dysmorphic syndromes such as Beckwith-Wiedemann syndrome.

### Umbilical Granulomas

At birth, the normal umbilical cord contains only the umbilical vessels surrounded by the protective Wharton jelly. Within the first 2 weeks after birth, the umbilical stump normally dries and separates from the abdomen; the region is completely covered by skin in 3 to 4 weeks. Delayed healing with the accumulation of excessive amounts of granulation tissue produces an umbilical granuloma, which is a small, reddened mass. The lesion may be associated with infection at its base or with a foreign body such as talcum, but it recedes rapidly after repeated topical applications of silver nitrate. Persistence of a granulomatous-seeming lesion after treatment, the presence of erosive dermatitis at the site, or the egression of gas, feces, or urine from it should suggest the persistence of one of the embryonic remnants described previously.

### Umbilical Polyps

Although polyps may superficially resemble umbilical granulomas, those at the umbilicus actually represent external remnants of the umbilical cord. They may be

## BOX 343-1 Some Conditions Associated With Umbilical Hernias

### CHROMOSOMAL ANOMALIES

- Opitz syndrome
- Weaver syndrome

sinuses of the vitelline duct or the urachus. Often larger in size than granulomas, umbilical polyps are bright red and do not respond to treatment with silver nitrate. Diagnosis depends on histologic examination, and treatment is surgical excision.

### Umbilical Separation

The umbilical cord normally separates and sloughs within the first 2 weeks of life. A delay in this process beyond 2 to 3 weeks of life may indicate an underlying abnormality. It is known that granulocyte influx and phagocytosis are important in the process of cord separation. In the event of delayed separation, 2 diagnostic considerations should be leukocyte adhesion deficiency (LAD) and urachal anomaly. LAD is a rare disorder of defective neutrophil function, often associated with omphalitis in infancy and with high morbidity and mortality. Urachal anomalies, such as urachal cyst (described previously), may also present with delayed umbilical separation.

## Chapter 344

# URINARY TRACT INFECTIONS

Gaurav Nanda, MD; Timo Jahnukainen, MD, PhD;  
Abhay Vats, MD

### INCIDENCE

Urinary tract infections (UTIs) are common in children. Approximately 2% of boys and 8% of girls experience at least 1 UTI episode by 10 years of age. Among febrile children of both genders, between 0 and 24 months of age the pooled prevalence of UTI is 7% (95% confidence interval [CI], 5.5%–8.4%).

The susceptibility to a UTI depends on a child's age and gender, with the highest incidence in children younger than 1 year. Boys constitute the majority of infants 6 months of age or younger with a UTI, and UTIs occurring beyond 6 months are most commonly seen in girls. Approximately 30% of children younger than 12 months are affected by recurrent infections

after their first UTI. The recurrence rate depends on the degree of vesicoureteral reflux (VUR); recurrences are more common in children with a higher (grade 3–5) degree of VUR. Most recurrences (85%) occur within 6 months after the primary episode of UTI.

Studies have shown that gender is not associated with risk for recurrence of UTI. In school-aged children, symptomatic UTIs are 5 times more common in girls than boys. Febrile UTIs (pyelonephritis) are more common in children younger than 12 months, whereas the most common presentation for UTI in older children is cystitis. Table 344-1 shows the common causative organisms and incidences of UTI for various age groups. The symptoms of cystitis and pyelonephritis in infants can be nonspecific and therefore difficult to recognize, which may partly explain the higher proportion of severe UTIs in the younger age groups.

### ETIOLOGY

#### Community-Acquired Infections

*Escherichia coli*, occurring naturally in the feces, is responsible for more than 75% of community acquired

**Table 344-1** Common Pathogens and Incidence of Urinary Tract Infection in Different Age Groups

AGE	GENDER	INCIDENCE (%)	COMMON ORGANISM	SYSTEMIC/PYELONEPHRITIS/CYSTITIS/ASYMPTOMATIC BACTERIURIA (%)

UTI cases (see Table 344-1). In neonates, UTIs caused by group B *Streptococcus* are more common, which perhaps reflects the colonization status of the mothers.

Other commonly occurring pathogens are *Klebsiella*, *Proteus*, *Enterococcus*, and coagulase-negative *Staphylococcus*, with each accounting for approximately 3% to 5% of cases. Genotypic analysis of pathogens causing second-time UTIs has shown that 65% of the recurrences are caused by the same pathogen that caused the first episode of UTI. The same bacteria were also found in the feces of patients, suggesting that the colon is a reservoir of uropathogenic bacteria. The prevalence of anatomic abnormalities of the urinary tract is significantly higher among patients with “complicated” UTIs, including those caused by non-*E coli* bacteria or those caused by nonvirulent *E coli* strains. Researchers have speculated that an anatomic or functional abnormality can enhance the invasion of bacteria with low virulence into the urinary tract.

### Non-Community-Acquired and Unusual Infections

Organisms such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should be considered as possible causes of UTIs in sexually active adolescents. These organisms most commonly cause lower tract (urethritis) infection. Multidrug-resistant *E coli* strains and non-*E coli* pathogens, including *Candida*, are the most common pathogens causing nosocomial infections. Most of these infections are associated with urinary tract instrumentation or catheterization, which makes critically ill children especially prone to UTI. Fungal infections are significant in patients with compromised immune systems or diabetes. Fungal overgrowth, however, may complicate antibiotic treatment of immunologically normal children with abnormal urinary tract emptying or those with indwelling urinary catheters. Symptomatic viral uropathogens are relatively uncommon except for adenovirus infections in patients with acute hemorrhagic cystitis. Several viruses, including adenovirus, polyomavirus, and cytomegalovirus, can also cause UTI and hemorrhagic cystitis in immunocompromised patients, especially those undergoing solid organ or bone marrow transplantation. Although protozoan infections of the urinary tract, especially schistosomiasis, are important in many parts of the world, they remain uncommon in the United States. Urinary infections with *Mycobacterium tuberculosis* occur rarely in secondary tuberculosis but should be considered when sterile pyuria is found in a suspected clinical setting.

### Pathogenesis

Generally, a UTI occurs when bacteria adhere to the uroepithelium and induce an inflammatory response. Situations that result in urinary stasis, such as obstructive uropathy, voiding abnormality, or constipation, predispose a child to the development of a UTI. Asymptomatic bacteriuria (ABU) is a condition with bacterial growth in urine culture but without symptoms or signs typical for UTI. ABU is generally detected on routine urine screening. Antimicrobial treatment is contraindicated; in fact, treatment may hasten the

development of a symptomatic UTI. Treatment usually includes management of the underlying voiding abnormality. The pathogenesis of UTI is, in most cases, considered to be by ascending route. The invasion of uropathogens may be restricted to the distal part of the urinary tract, causing urethritis or cystitis (ie, lower UTI), or they may reach the upper urinary tract, causing ureteritis and pyelitis or pyelonephritis (or both) (ie, upper UTI). The probability and level of UTI depends on the virulence factors of the bacteria and on the defense mechanisms of the host. Rarely, UTIs in infants are hematogenous (eg, associated with sepsis) rather than ascending in origin.

Bowel and bladder dysfunction (BBD) is known to be a significant risk factor for UTI and recurrent infections. Although detrusor instability is often associated with BBD, infrequent voiding along with large postvoid residual urines are the main causes of recurrent UTI in this group. Children with BBD have a form of rectal and urethral sphincteric dyssynergia resulting in holding both urine and stool. Hence, they are typically constipated and have recurrent UTIs. This can be most reliably identified by a toileting diary and questionnaire. BBD can be treated using cathartics and biofeedback therapy in older toilet-trained children.

### Bacterial Virulence Factors

The uropathogenicity of bacteria depends on the presence of virulence genes, which determine their adhesive capacity and ability to cause tissue damage by toxin production. The expression of these genes varies among different strains. Bacterial adhesion depends on the presence of fimbriae or pili on the surface of the pathogen. Adhesins, which are situated at the tips of the bacterial fimbriae, recognize specific receptors on uroepithelial cells and enable adhesion to these cells. Bacterial toxins also have an important role in inducing inflammation and tissue damage in the host. These factors influence the severity of symptoms, such as fever or dysuria, and the long-term effects of UTI (renal cell damage and scarring). Several *E coli*-derived toxins have been recognized, but their exact role in UTIs remains unclear.

### Host Defense

Local and systemic host defense mechanisms are relatively effective in preventing UTI. Uroepithelium forms a physical barrier against microorganisms. In addition to providing a passive shield, uroepithelium produces antimicrobial proteins and responds to bacterial invasion by activating the immune cascade. Under physiologic conditions, overgrowth of uropathogenic bacteria at the periurethral area is controlled by colonization of low-virulence bacterial strains that are considered to be normal flora. Disturbances in normal periurethral flora can allow enrichment of pathogenic bacteria, leading to their spread into the urinary tract. Most bacteria entering the urinary tract are eliminated by the wash effect of urine flow. Adherence of remaining bacteria is decreased by antibodies (immunoglobulin A) and Tamm-Horsfall protein. Pathogens that survive this first line of defense can later adhere to the urothelium. These

organisms then face the next level of defense mechanism, which is a set of proteins called *defensins*. However, the exact mechanism by which defensins kill the microorganisms is unclear. Once the pathogens cross the mucosal barrier, they may be cleared by the systemic immune defense mechanisms. Local production of inflammatory chemokines and cytokines represents an important defense mechanism of the uroepithelium during acute infection. Abnormalities in any of the defense layers can predispose a person to develop UTI. Frequent bladder emptying, especially relevant in infants, is another important defense mechanism against the development of UTI. Acidic pH and high urine osmolality and urea may also impede the growth of bacteria.

The role of circumcision in preventing UTIs has also been debated. The intact foreskin has been implicated in the cause of UTIs in boys younger than 1 year. Circumcision reduces the risk for UTI. Newborn circumcision has been reported to result in an almost 10-fold decrease in the incidence of UTI during the first year of life. The possible benefits of circumcision can be explained partly by better penile hygiene compared with uncircumcised boys. No clear recommendation about circumcision is currently available; however, it can be considered in boys with recurrent UTIs.

A consensus seems to be emerging that the health benefits of newborn male circumcision outweigh the risks, but the benefits are not great enough to recommend universal newborn circumcision. Therefore, the final decision should be left to parents to make in the context of their religious and cultural beliefs. (See Chapter 89, The Circumcision Decision.)

## EVALUATION

### History

The clinical presentation of a UTI depends on the age of the child, virulence of underlying pathogen, and inflammatory response of the host. Dysuria, frequency, urgency, and lower back pain are the symptoms most often associated with UTIs. However, in young children, especially in infants, the symptoms of UTI are variable and nonspecific. Fever is an important sign in infants and children younger than 2 years. Even a bacteremic UTI can be clinically indistinguishable from other types of infection in very young children. This ambiguity may sometimes lead physicians to think of alternate possibilities, causing a delay in diagnosis and appropriate treatment.

In children older than 5 years, the classic symptoms of a UTI—urgency, frequency, and dysuria—are often present. Children younger than 4 years may not reliably be able to localize pain or report their precise symptoms, although some parents can detect symptoms suggestive of UTI in these children. By age 4 years, a child's capability to report specific symptoms such as abdominal pain or dysuria improves. A UTI should always be considered as a possible cause of unexplained fever and should always be included in the sepsis workup of seriously ill infants and younger children. With some caveats, fever can be used as a rough estimate of the level of UTI. A body temperature less than 38°C (100.4°F) suggests cystitis, whereas a

fever of 38.5°C (101.3°F) or more most often is associated with an upper UTI. In newborns, however, normal body temperature does not exclude the possibility of upper UTI, and the newborn with a UTI may occasionally be hypothermic. Fever can be an inconsistent finding and exists in only approximately 10% to 40% of UTI cases in children younger than 2 years. In these cases, other symptoms such as vomiting, irritability, abnormal crying, lethargy, failure to thrive, and feeding problems should be considered as indications for a urine screening.

### Physical Examination

The physical findings of a child with a UTI vary depending on the severity of the infection and the age of the patient. Especially in infants, the findings are nonspecific and are rarely suggestive of a definitive diagnosis. In addition to fever, other findings suggestive of septicemia, including irritability, abnormal crying, peripheral cyanosis or hypothermia, and prolonged capillary filling time, can be seen in young infants. Tenderness on palpation of the abdomen in the suprapubic region can be found in those with cystitis, whereas costovertebral angle tenderness is elicited in older children with pyelonephritis. However, the absence of these findings does not rule out the possibility of a UTI.

An examination of the urethral meatus should be included in the physical examination of every child with a suspected UTI. In some cases, dysuria can be caused by local inflammation or irritation of the external genitalia. The external genitalia in girls should be examined carefully, given that labial adhesions are often associated with UTIs.

### Laboratory Testing

A correct diagnosis is crucial for the successful treatment and follow-up of a child with a UTI. An incorrect diagnosis of UTI may lead to missing a potentially harmful urinary tract abnormality or to unnecessary studies, costs, and stress. A UTI must be always confirmed by an adequate urine collection for urinalysis and culture.

### Urine Collection

Adequate urine collection is essential for a correct diagnosis. All samples should be collected and stored to prevent contamination and then analyzed carefully. If a febrile child with a suspected UTI cannot provide a clean-catch urine, the urine specimen should be obtained through catheterization or suprapubic aspiration before antimicrobial treatment is started. The diagnosis of a UTI cannot be established reliably through the culture of urine collected in a bag. Sample collection at home is discouraged because of the high risk of contamination. The urine samples should be kept at 39.2°F (4°C) unless a culture is performed less than 1 hour after voiding.

Before micturition, the periurethral area and surrounding skin should be washed and dried properly. When the urine sample is obtained through bladder catheterization or voiding, the first few drops should be allowed to fall outside the sterile container, because they may be contaminated by bacteria in the

### BOX 344-1 Guidelines for Suprapubic Percutaneous Aspiration of Urine

- Indications
  - Verification of urinary tract infection in newborns and infants
  - Sepsis workup in critically ill children
- Equipment
  - 21- to 25-gauge needle
  - 5- to 10-mL syringe
  - lidocaine/prilocaine cream
  - Sterile gloves
  - Portable ultrasonography equipment
- Technique
  - Ensure that there is urine in the bladder, optimally with an ultrasound. Alternatively, careful observation that the child has not voided for at least 45–60 minutes should occur.
  - Put a small amount of lidocaine/prilocaine cream on a circle area (~3 cm) approximately 2–3 cm above symphysis midline; wait about 30 minutes.
  - Set child in a supine position.
  - Clean the patient's skin with antiseptic solution.
  - Insert needle percutaneously at approximately 1 finger's breadth above the symphysis pubis.
  - Advance slowly with continuous suction; usually urine is obtained at the depth of 2–3 cm
- Complications
  - Generally safe and reliable with an experienced operator
  - Occasionally transient hematuria (2%–3%)
  - Intestinal puncture not harmful

distal urethra. The cultures of urine samples collected via bag applied to the perineum have a very high false-positive rate. They are valid only when they yield negative results. In incontinent children, a urine bag or absorbent pad are avoided because of the high risk of contamination. Urine contamination rates are similar for bag and pad (75% of positive cultures) and are significantly higher than for clean-catch urine, catheterization, or suprapubic aspiration. Positive culture results from a urine bag or urine pad sample should always be verified by catheterization or suprapubic aspiration (see Box 344-1 and Box 344-2). A negative culture result from a urine specimen collected by bag or pad does exclude UTI. For toilet-trained children and adolescents, the midstream urine sample is preferred for culture. If the child is critically ill, then suprapubic aspiration or catheterization is preferred in all age groups.

#### Urine Culture

The diagnosis of UTI is confirmed by the growth of a single pathogen on urinary culture and significant pyuria on urinalysis. The bacteria level that is considered significant depends on the method used for urine

### BOX 344-2 Steps for Transurethral Bladder Catheterization

- Restrain the child in the supine and frog leg position, because this position permits adequate stabilization of the pelvis and complete visualization of the external genitalia.
  - Cleanse the anterior urethra thoroughly with povidone-iodine solution.
  - Apply a sterile lubricant jelly to the end of an appropriately sized catheter
- Following are the urinary catheter sizes recommended by age:
- 5 French for children younger than 6 months;
  - 8 French for those between 6 months and adolescence
  - 10 French for adolescents
  - If a topical anesthetic is used, it should be applied 2–3 minutes before the procedure is performed. However, the efficacy of using topical lidocaine to reduce pain during urethral catheterization in children remains uncertain.

#### BOYS

- In uncircumcised boys, retract the foreskin of the glans gently to permit complete visualization of the urethral meatus
- Straighten the urethra by using the nondominant hand to hold the penis perpendicular to the lower abdomen and apply gentle traction.
- Insert the catheter with the dominant hand until urine returns.
- Advance the catheter and continue to palpate it along the posterior aspect of the penis. Maintain traction on the penis, while applying gentle pressure with the catheter. The catheter should never be forced.
- Reduce the foreskin to its normal position so that a paraphimosis does not develop in uncircumcised boys.

#### GIRLS

- The urethra may be difficult to visualize in girls, and an assistant often is needed to retract the labia majora. Have the assistant lift the labia majora anteriorly, laterally, and cephalad. Swab the area from front to back; this may help push this tissue out of the way and permit the povidone-iodine solution to pool in the meatus, thus making identification easier.
- Insert the catheter into the urethral meatus until urine returns.
- Discard the first few drops of urine obtained to prevent contamination of the urine with urethral organisms or cells. This will help decrease the false-positive results on urinalysis for white blood cell counts and bacteria detection.

collection. For voided samples (clean-catch urine, urine bag, and absorbent pad), a bacterial count of 100,000 or more colony-forming units (CFU)/mL is considered significant. Bag and absorbent pad cultures are not accurate and must be confirmed as stated earlier. The new American Academy of Pediatrics (AAP) UTI guidelines indicate that counts greater than 50,000 CFU/mL are diagnostic for UTI. The

contamination risk for catheterization and suprapubic aspirate is considerably lower than for a clean-catch specimen, and therefore any bacterial growth in suprapubic aspirate or a bacterial count of 50,000/mL or more in a catheter sample is indicative of a UTI. Urine cultures showing growth of more than 1 pathogen should be considered as contamination, and a repeat sample is required before starting any treatment.

### Urinalysis

The results of a urine culture are not generally available on the same day that the sample is collected, which may cause a delay in diagnosis. A urinalysis showing leukocyturia can support the diagnosis of UTI. However, a urinalysis is not sufficient by itself to diagnose a UTI, because leukocytes may be present in the urine (pyuria) for several reasons besides UTI.

Pyuria is defined as 10 or more leukocytes/mcL in an uncentrifuged urinary specimen. A count of less than 10 leukocytes/mcL is almost invariably associated with a sterile urine culture, whereas a count of 10 or more leukocytes/mcL is found in 90% of patients with bacterial growth of 50,000 or more CFU/mL. A high urinary leukocyte count is very sensitive (about 95%) but not specific for the presence of a UTI. A UTI can also be an important cause of microscopic hematuria. However, the presence of red blood cells in urine does not have diagnostic or prognostic value. The leukocyte esterase test has a sensitivity of about 83% when used in the context of a clinically suspected UTI. Some studies have reported a lower sensitivity, because the results of leukocyte esterase tests were related to culture without the exclusion of children with ABU. Either a positive leukocyte esterase or a positive nitrate is highly suggestive of a UTI, with a sensitivity of 93% and a specificity of 72%. The combination of leukocyte esterase test and a positive nitrite test does not improve sensitivity (78.7%) but increases the specificity (98.3%). A combination of cell counts and a Gram stain has more sensitivity (87.7%) and specificity (99.2%) when assessing the risk for a UTI. Combining the leukocyte esterase test plus a nitrite test or urine microscopy significantly increases the sensitivity (99.8%). A nitrite test is usually positive if the bacterial counts are high enough (>100,000 CFU/mL). However, there are several reasons why a urinary nitrite test may be negative in the presence of a UTI. First, the chemical reaction (conversion of nitrates to nitrites) requires that urine be present in the bladder for at least 4 hours. In addition, not all organisms convert nitrate to nitrite. Overall, only about 50% of UTIs will feature a positive urine nitrite test.

### Determining the Location of a Urinary Tract Infection

The reliable differentiation of an upper UTI from a lower UTI can be difficult; however, several investigations or findings can help make this distinction. Only 55% to 85% of children with a febrile UTI have changes on radionuclide studies, such as 99m technetium dimercaptosuccinic acid (DMSA) scan, which has been suggested to be the gold standard for diagnosing pyelonephritis. In addition, infants may have an

afebrile bacteremic UTI. However, a fever of 38.5°C (101.3°F) or higher, increased levels of C-reactive protein ( $\geq 40$  mg/L), and leukocytosis should suggest pyelonephritis. Several biomarkers are currently being evaluated as possible indicators for an upper UTI. Procalcitonin is one such marker and has recently been proposed as a possible indicator for pyelonephritis. Increased serum procalcitonin levels have been shown to correlate significantly with renal parenchymal involvement in children with febrile UTI. This method, however, is not currently routinely available or used in the diagnostic testing of UTI. No correlation between the level of UTI and serum electrolyte and creatinine concentrations has been reported. However, these serum electrolytes and creatinine parameters should be measured in febrile infants or children with associated symptoms such as vomiting or diarrhea to assess the level of hydration or other attendant complications.

## IMAGING STUDIES

Children with UTIs are more often found to have anatomic abnormalities in the kidneys or in the urinary tract, such as obstructive disorders and VUR. The highest risks for significant urinary tract abnormalities are in children younger than 1 year and in children with non-*E coli* UTI versus those with *E coli*-associated UTI. Imaging studies of the urinary tract are no longer recommended for all children with a first-time UTI but should be focused on high-risk patients. The imaging studies for UTI include renal and bladder ultrasonography (RBUS), voiding cystourethrography (VCUG), and DMSA scan.

A summary of indications for various imaging studies for children with a suspected UTI is found in Box 344-3. The AAP recommends that infants 2 to 24 months of age with first-time febrile UTI should be studied by means of RBUS. The timing of RBUS can

### BOX 344-3 Indications for Imaging Studies in Children

#### ULTRASONOGRAPHY

- First-time febrile UTI and age 2–24 months (AAP guideline)
- Atypical UTI, all ages (NICE guideline)
- Recurrent UTI, all ages (NICE guideline)

#### VOIDING CYSTOURETHROGRAM

- First-time febrile UTI, abnormal RBUS, complex clinical circumstances and age 2–24 months (AAP guideline)
- Atypical UTI and age <6 months (NICE guideline)
- Recurrent UTI and age <6 months (NICE guideline)

#### DMSA SCAN

- Atypical UTI and age <3 years (NICE guideline)
- Recurrent UTI, all ages (NICE guideline)

DMSA, dimercaptosuccinic acid; NICE, National Institute for Health and Clinical Excellence; RBUS, renal and bladder ultrasound; UTI, urinary tract infection; VUR, vesicoureteral reflux.

be decided based on clinical situation. If fast clinical improvement is achieved, the RBUS can be delayed until full recovery; however, if there is no clear response to treatment within 48 hours, acute RBUS should be performed. This helps in identifying complications such as renal and perirenal abscesses and pyonephrosis. In children 2 to 24 months old, VCUG is indicated when RBUS reveals hydronephrosis, scarring, or other findings suggesting high-grade VUR or obstruction of the urinary tract. When indicated, the VCUG can be done within a week of diagnosis. There are currently no AAP recommendations about imaging studies after UTI in older children and in infants and children with afebrile UTI. Because the probability of imaging studies to reveal factors predisposing the patient to renal damage is relatively low in children older than 2 years and in children with uncomplicated UTI, the indications for imaging studies are therefore scarce. These factors could be recurrent UTI, non-*E coli* infection, or a positive family history. The present recommendations may change when the results of ongoing multicenter studies in the United States and other countries are available.

### Renal and Bladder Ultrasound

The RBUS is the least invasive and most widely available imaging modality that can be performed during the acute phase of a UTI. It can detect dilated collecting system, thinning of kidney parenchyma, the size of the kidneys, and the thickness and size of the urinary bladder. However, ultrasonography may not be able to detect VUR or smaller renal scars. The reliability of ultrasonography is highly dependent on the experience of the radiologist. The need for ultrasonography after UTI has been questioned. It has been suggested that ultrasonography results may have little or no influence on the treatment of children with UTI because of routine prenatal ultrasonography. The widespread use of maternal-fetal ultrasonography in industrialized countries has possibly lessened the need for ultrasonography later in childhood. However, several studies have shown that a significant kidney or urinary tract abnormality may be missed in spite of a prenatal RBUS in 5% to 6% of the children with a first-time febrile UTI and that abnormal RBUS predicts risk for renal scarring. These findings suggest that the RBUS will probably continue to play a major role as a primary imaging study after first-time febrile UTI in children.

### Voiding Cystourethrography

VCUG is traditionally used to diagnose VUR, which predisposes patients to pyelonephritis and recurrent infections and may be associated with renal scarring. VUR is graded from I to V (Box 344-4). The incidence of VUR is highest in children younger than 2 years. A VCUG can be performed using either radiopaque medium or radiolabeled nuclides. A contrast voiding cystography is usually preferred in boys because it is more reliable than other methods in detecting urethral valves, and it allows more exact grading of reflux. Cystography requires catheterization, which is relatively invasive and stressful, especially in older children. Cystography exposes children to radiation, and it is

relatively laborious and costly. Moreover, evidence suggests that a low-grade VUR (grade < 3) itself is not a significant risk factor for renal damage and that antimicrobial prophylaxis is not effective in preventing renal damage in children with VUR. For these reasons, the use of cystography has dramatically decreased in recent years. According to the current AAP recommendation, VCUG should not be performed on a routine basis after a first febrile UTI. It should be performed in children 2 to 24 months old if RBUS shows evidence of hydronephrosis, scarring, or other findings that would suggest either high-grade VUR or obstructive uropathy. The National Institute for Health and Clinical Excellence (NICE) guideline from the United Kingdom has restricted cystography only to children less than 6 months old with atypical UTI (dilation on ultrasound, poor urine flow, non-*E coli* infection, family history of VUR). A VCUG should, however, be considered in children presenting with complex clinical circumstances. VUR spontaneously resolves in a high proportion of children, especially in those with grades I–II VUR; hence, isotope voiding cystography is recommended every 1 to 3 years until resolution of VUR is documented. VCUG should be considered if there is a positive family history of VUR, if the urinary tract dilation is detected prenatally, or there is a history of complicated or recurrent pyelonephritis.

### Dimercaptosuccinic Acid Scan

One of the most reliable methods to differentiate pyelonephritis from lower UTI is a DMSA scan. DMSA is a radionuclide that is taken up by renal tubular cells and provides information on functional anatomy as well as scarring of renal parenchyma. It is more often abnormal in patients with documented reflux than in children without VUR. Based on these results, some authors, including the authors of the NICE clinical guideline, suggest that the DMSA scan should be performed 4 to 6 weeks following the first-time UTI in all children younger than 3 years with atypical UTI or recurrent UTIs and in children older than 3 years with recurrent UTIs. Recurrent UTI has been defined as 2 or more episodes of upper UTI, or 1 episode of upper UTI plus 1 or more episodes of lower UTI, or 3 or more episodes of lower UTI. This approach has likely reduced the number of VCUGs performed by

#### BOX 344-4 International Classification of Vesicoureteral Reflux

- Grade I: involves only ureters
- Grade II: involves ureters and intrarenal collecting systems
- Grade III: mild ureteral and pelvic dilatation; no or slight obliteration of caliceal fornices
- Grade IV: moderate ureteral and pelvic dilatation; clear obliteration of caliceal fornices
- Grade V: gross dilation of ureters and renal pelvis and calyces

approximately 50% without adding any major risk for the patient. The AAP guideline does not recommend a routine DMSA scan after the first UTI in children.

## TREATMENT

The cornerstones of the successful treatment of a UTI are early recognition and early, appropriate treatment. Before initiating treatment, adequate samples of urine should be collected for culture and for determining the antibiotic sensitivities of the organisms. If the patient has sepsis or dehydration, then adequate rehydration should coincide with antibiotic therapy. The route of antibiotic administration (oral or parenteral) depends on the age and clinical condition of the patient (Figure 344-1).

### Pyelonephritis

Infants younger than 1 year are usually hospitalized and treated with parenteral antibiotics followed by oral antibiotic therapy for a total of 14 days. However, oral antibiotics (for patients who can tolerate them) are as effective as parenteral antibiotics even in young children with a febrile UTI. Hence, if the child with a UTI does not seem to have sepsis and is able to tolerate oral medications, initial treatment with an oral antibiotic might possibly be appropriate. However, follow-up is essential to ensure complete recovery. Infants younger than 2 months should be hospitalized in all instances.

### Cystitis

Assuming adequate liquid intake and an ability to tolerate antibiotics, oral therapy alone is usually adequate to treat cystitis. The first-line therapy for outpatient treatment of a UTI usually consists of amoxicillin plus clauvalunnic acid, cephalosporin, or trimethoprim-sulfamethoxazole (TMP-SMX). It is important to know the sensitivity patterns of common UTI-causing organisms in a given geographical area in order to select the most effective initial agent before sensitivity results are available from urine culture. The suggested dosing is shown in Table 344-2; 5 days of treatment with appropriate antibiotics is adequate for children younger than 2 years who are afebrile and have uncomplicated cystitis.

### Asymptomatic Bacteriuria

Studies involving infants and schoolgirls have shown that untreated ABU does not increase the risk for pyelonephritis or renal damage. In fact, children treated with antibiotics for ABU can have a higher incidence of pyelonephritis than untreated children. Researchers have suggested that pathogens causing ABU have low virulence, which may protect against an overgrowth of uropathogenic bacteria. Current recommendations are that it should not be treated with antibiotics. Children who undergo intermittent catheterization or those with neurologic bladder dysfunction frequently have ABU, but are asymptomatic and often do not have leukocyturia.

### Prophylaxis

Prophylactic antibiotics are no longer recommended for all children after their first UTI. The efficacy of prophylactic antibiotics has been questioned based on recent reports showing that use of low-dose

antimicrobial treatment does not necessarily reduce the number of recurrent infections or protect against renal scarring. On the contrary, the prolonged use of antimicrobials may lead to development of bacterial resistance. Prophylaxis should be considered for children with an increased risk of UTI; that is, children with higher grades of VUR (grades III–V), especially with bowel and bladder dysfunction or obstructive uropathy and previous history of UTI or recurrent UTIs (3 febrile UTIs/6 months or 4 total UTIs/year). The most common prophylactic regimen is of cotrimoxazole (TMP-SMX [2 mg of TMP and 10 mg of SMX/kg/day]) or nitrofurantoin (1–2 mg/kg/day) as a single daily bedtime dose. The duration of prophylaxis depends on the indication. In children with VUR, especially older children, the prophylaxis is usually continued until reflux has resolved or has been surgically corrected and the child has been free of symptoms and bacteriuria for at least 1 year.

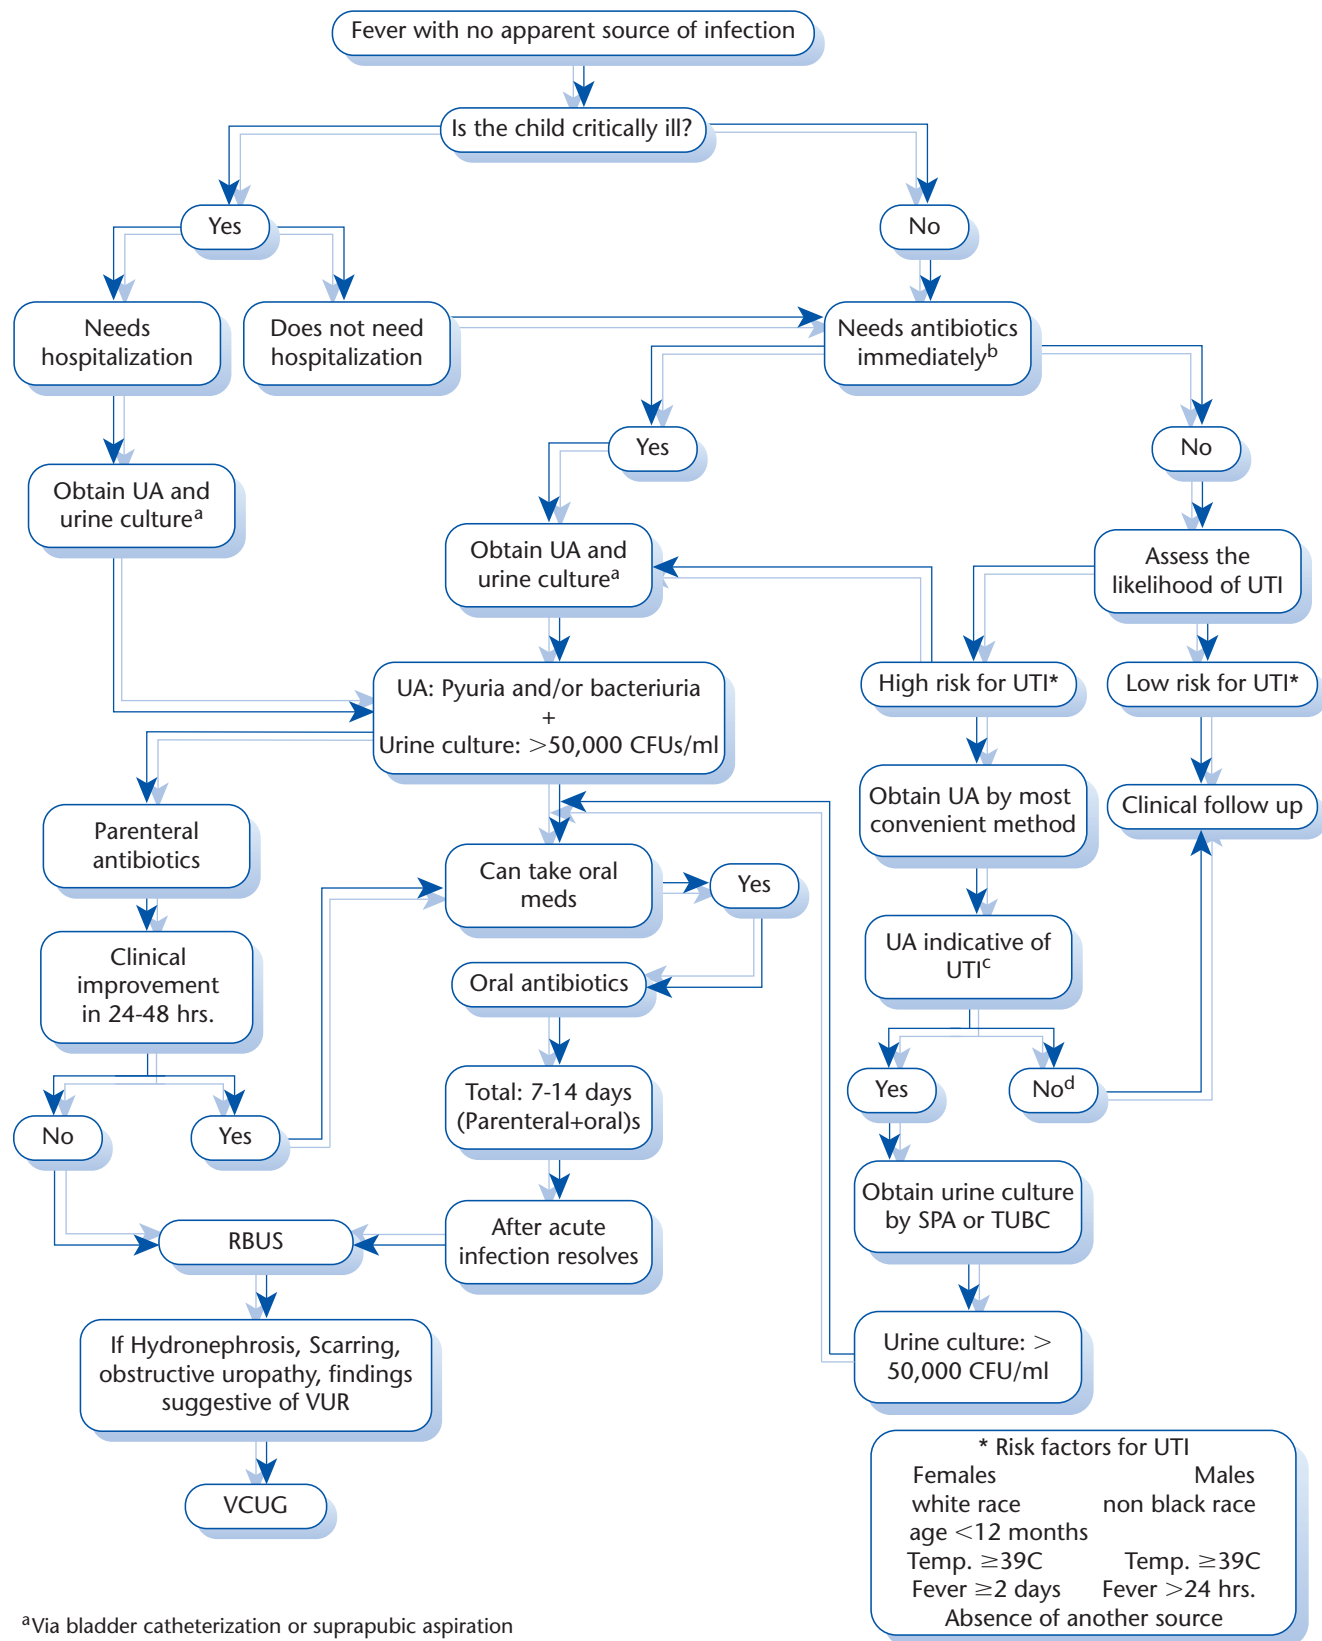

### Supplemental Therapy

Constipation and encopresis are known to be risk factors for UTI and should be especially anticipated in children with recurrent UTI. Treatment of these problems by behavioral and dietary modification or medication is important to prevent recurrent UTIs. Besides constipation, the role of circumcision in preventing UTI has also been studied. Although the relative risk of UTI in uncircumcised male infants compared with circumcised male infants is increased from 4-fold to as much as 10-fold during the first year after birth, the absolute risk of developing a UTI in an uncircumcised male infant is low (at most, approximately 1%). Currently, the health benefits are not great enough to recommend routine neonatal circumcision.

## COMPLICATIONS—RENAL SCARRING

Isotope uptake studies (DMSA scans) have shown that the renal parenchyma is affected in approximately 55% to 75% of children with a febrile UTI. Approximately 15% to 40% of these children will develop permanent renal parenchymal damage; that is, renal scarring. In a recent meta-analysis of 33 published studies, of all children with an initial episode of UTI, 57% had changes consistent with acute pyelonephritis on the acute-phase DMSA renal scan and 15% had evidence of renal scarring on the follow-up DMSA scan. VUR is a major determinant of the development of renal scars. Children with VUR were significantly more likely to develop pyelonephritis (relative risk [RR], 1.5 [95% CI, 1.1–1.9]) and renal scarring (RR, 2.6 [95% CI, 1.7–3.9]) compared with children with no VUR. Children with VUR grades III or higher were twice as likely as children with lower grades of VUR to develop scarring.

In some cases, renal disease may be congenital rather than acquired and therefore not dependent on UTI. In an analysis of 1,221 children with a first-time UTI, the incidence of permanent renal damage was 86% in boys and 30% in girls. The mean age of boys at the time of a UTI was significantly lower compared with girls, and VUR was present in 67% of the boys and in only 19% of the girls. Infants (mean age, 4 months) with high-grade VUR without a UTI have been shown to have fewer scars than patients with VUR

and a history of UTI. In children with high-grade VUR, UTI, and renal damage, determining the exact contribution of congenital factors, reflux, and infection to renal dysfunction may be difficult. The risk factors for renal parenchymal damage include gross VUR, young age at the time of first infection, delayed initiation of treatment, and recurrent infections.

### LONG-TERM EFFECTS OF URINARY TRACT INFECTION

A UTI is generally considered an infectious disease with a very good prognosis. If no renal abnormalities are found in imaging studies performed after a first childhood UTI, it appears unlikely that subsequent childhood UTIs will cause chronic kidney disease later in life. Although most children with UTIs have no long-term consequences, several sequelae can be associated with UTIs. A small risk exists of permanent renal damage, which may increase the risk of hypertension and ultimately cause varying degrees of renal failure. A UTI may also increase the risk of pre-eclampsia during pregnancy. The risk for end-stage kidney disease, however, is relatively small in children with UTI without structural anomalies. According to the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) ([www.naprtcs.org](http://www.naprtcs.org)), which collects data on pediatric patients with renal failure in the United States, pyelonephritis (without known structural disease) or interstitial nephritis accounts for renal failure in only 1.8% of all patients who require renal transplantation. The respective numbers

for obstructive uropathy, renal hypoplasia or dysplasia, and reflux nephropathy are 16.1%, 16%, and 5.2%, indicating that anatomic abnormality with or without UTI is a more important threat to kidney function than the UTI itself. Hypertension remains an uncommon and important long-term complication of childhood UTI, but its incidence may be lowered by careful attention to risk factors and early treatment. Bacteriuria and symptomatic UTI are significantly more common in pregnant women with a history of childhood UTI. A UTI may also contribute to increased risk for pre-eclampsia (hypertension and proteinuria) and may be harmful for the fetus and cause premature labor.

#### WHEN TO REFER

- Abnormal findings on imaging
- VUR
- Frequently relapsing UTIs
- Suspicion of voiding dysfunction
- Renal insufficiency (elevated creatinine)
- Hypertension

#### WHEN TO ADMIT

- Suspected urosepsis
- Infant younger than 3 months with UTI
- Suspected UTI in dehydrated patient or patient unable to retain oral fluids
- Patient whose symptoms worsen or do not improve despite oral treatment

## Chapter 345 VERRUCAE (WARTS)

Catherine Chen, MD; Judith V. Williams, MD

## VERRUCAE (WARTS)

Verrucae (warts) are virally induced tumors of the skin. They are a frequent cause of physician office visits. Cutaneous warts affect up to 10% of children between 2 and 12 years of age and rank among the top 3 dermatoses in this age group, with no gender

predilection. Genital warts are uncommon in children before puberty but represent one of the most common sexually transmitted infections in adolescents and adults.

### Etiology

The wart virus is a human papillomavirus (HPV) that infects epidermal cells and causes focal epidermal proliferation, expressed clinically as a verrucous papule.

More than 100 types of HPV have been characterized, and the number continues to grow. Specific types have been associated with specific warts. For example, HPV types 1 (HPV-1), 2, and 4 are found in plantar warts; HPV-2 and HPV-7 in common warts; HPV-3 and HPV-10 in flat warts; HPV types 1, 6, and 11 in benign genital warts; HPV types 6, 7, 11, 16, and 32 in laryngeal papillomas; and HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68 in genital warts that have malignant potential (eg, cervical carcinoma). Thus, HPV typing holds promise in helping identify premalignant warts, as well as sources of the transmission of warts.

### Epidemiologic Features

The wart virus is presumably inoculated into the skin from some external source, but usually neither the source nor event of inoculation is elicitable. Frogs and toads have been unfairly incriminated as carriers. However, asking about and searching for warts on other areas of the body is reasonable; for example, patients who have warts on their lips often have them on their fingers. Given that warts are transmissible, other family members may also have them.

In young infants, warts (including those in laryngeal and genital locations) are assumed to have been acquired from the mother's vaginal tract during delivery. Genital warts in children can raise the question of sexual abuse. No clear age exists below which sexual abuse is not a concern; however, several recent studies of anogenital warts in children found no evidence of sexual abuse in most of the subjects younger than 3 years. Based on HPV typing, anogenital HPV infection in most infants seems to be acquired either by nonsexual transmission or perinatally. In fact, a study demonstrating a high incidence of HPV-2 in anogenital warts in prepubertal children suggested that innocent autoinoculation or heteroinoculation from cutaneous warts may be a common means of acquisition. Evidence also exists pointing to the possibility of in utero transmission of HPV, although the exact mechanism (hematogenous, infected semen at fertilization, ascending maternal infection) is unclear. A complete social history and thorough physical examination may be helpful in determining the need for evaluation for possible sexual abuse.

Patients who have systemic defects in cell-mediated immunity are more susceptible to warts, which are often recalcitrant to treatment. In addition, because cellular immune responses in the skin are impaired with atopic dermatitis, these patients, too, have more difficulty with warts and other viral infections of the skin.

### Prevention

Gardasil, a vaccine for HPV types 6, 11, 16, and 18, which together cause 70% of cervical cancers and

90% of genital warts, was approved by the US Food and Drug Administration (FDA) in June 2006 for use in female patients 9 to 26 years of age. In October 2009, it was then approved for use in male patients 9 to 26 years of age to prevent genital warts resulting from HPV types 6 and 11. It is administered 3 times over a 6-month period. The question about whether it should become mandatory or remain voluntary is currently being addressed at the state level.

### Clinical Findings

#### Physical Findings

The clinical appearance of warts varies, depending on the type and location. The common wart, or *verruca vulgaris*, is easily recognized as a superficial, light-colored papule that has a coarse, roughened surface. Warts are often studded with black specks, which many patients call *seeds*, but which are actually small, superficial dermal capillaries. Warts are sometimes found in linear array, presumably as a result of autoinoculation through scratching. Not all warts appear as verrucous papules. Variants include flat (planar) warts, plantar warts, periungual warts, and anogenital warts.

#### Laboratory Findings

Warts are almost always diagnosed clinically. If doubt exists, then a skin biopsy can provide histologic confirmation.

#### Differential Diagnosis

The distinctive clinical appearance of the common wart usually presents no problem in diagnosis. Although epidermal nevi, which are hamartomas, may be confused with warts, they are usually softer, more pigmented, more persistent, and much less common. Flat (planar) warts appear as small, flesh-colored papules (Figure 345-1). When located on the face, flat warts are often confused with the closed comedones (whiteheads) seen in acne. On very close inspection, however, flat warts are seen to have sharp borders and a finely verrucous surface, whereas closed comedones are smooth, dome-shaped lesions.

**Figure 345-1** Flat warts. Flat warts may be confused with comedones.

Plantar warts are so named because they appear on the plantar surface of the foot (Figure 345-2). They are often confused with calluses and corns, although corns are much less common in children than are warts. Large plantar warts are often composed of confluent smaller warts, which form a mosaic wart surrounded by satellite lesions. Additionally, plantar warts differ from corns by having a verrucous surface that interrupts skin markings and are often punctuated with black specks. In some cases, the 2 entities can only be distinguished by paring down the surface; wart tissue still has a roughened texture, whereas a corn is smooth. A corn also becomes smaller in diameter as it is pared; a wart does not.

Periungual warts that occur around the nail fold should not pose diagnostic difficulty. Warts under the free edge of the nail, however, can cause the nail plate to separate from the nail bed and may be confused with a fungal infection. On close inspection, the verrucous nature of the wart usually can be appreciated.

Anogenital warts (*condylomata acuminata*) are sometimes, but not always, acquired by sexual contact. They can usually be easily identified as verrucous papules (Figure 345-3), but they are sometimes small or flat and, therefore, more difficult to see. In this situation, the acetowhitening technique can aid in the diagnosis. A compress containing 5% acetic acid is applied for several minutes to the suspected area, which is then reexamined, ideally under magnification. With this technique, warty tissue turns white and thus is visualized more easily.

Genital warts may be confused with the less common *condylomata lata*, skin lesions found in secondary syphilis. In general, *condylomata acuminata* are drier and usually more verrucous than *condylomata lata*, which are flat and moist. If doubt exists, then a serologic test for syphilis can confirm the diagnosis.

### Psychosocial Considerations

Among school children, warts are often a focus for teasing and insensitive remarks. Consequently, when children ask that their warts be treated, they usually

**Figure 345-2** A mosaic plantar wart with a roughened surface punctuated with black specks.

do so because of social pressure. Successful therapy gives patients the opportunity to feel better about themselves and their appearance.

### Management

Over the years, a wide variety of treatments have been recommended, including some interesting unproven approaches, such as applying banana peels or slices of raw potato, which probably seem to work because most warts eventually regress spontaneously. One prospective study of untreated common warts in children showed that two-thirds of the warts underwent spontaneous regression within 2 years. This finding must be kept in mind when physicians credit their treatment for a successful result. Nonetheless, when a patient requests treatment of a wart, physicians are usually inclined to oblige. However, because a specific antiviral medication for warts has not yet been developed, physicians still rely on nonspecific destructive techniques as therapy; the following techniques are used most often.

### Cryotherapy

Tissue is frozen by applying liquid nitrogen ( $-195^{\circ}\text{C}$ ) to the wart either with a swab or through a canister delivery system. The freeze should extend beyond the wart to include a 1- to 2-mm rim of normal skin. To destroy affected tissue more effectively, the wart may be refrozen after the initial thaw. The patient must be advised that the frozen area will be sore for several days, a blister may form, and several weeks are usually needed for the wart to turn dark and drop off. Cryotherapy is a frequently used office therapy for common warts. For small warts, a single treatment is often successful, but large warts frequently need to be refrozen approximately every 3 weeks. Scars may result, but are uncommon. The skin may also become

hypopigmented. When freezing warts on the fingers, care must be taken to avoid freezing too deeply because underlying structures such as digital nerves can be damaged. Over-the-counter freezing treatments are now available, but these products may not be as effective as liquid nitrogen.

### Keratolytic (Acid) Therapy

Acid therapy is slower and involves more patient participation than freezing, but it is less immediately painful and is least likely to cause scarring. A variety of acids are available for treating warts. Salicylic acid is available as a solution in 26% (Durasal) and 27.5% (Virasal) concentrations. A convenient outpatient medication incorporates 17% salicylic acid in a polyacrylic or flexible collodion vehicle (Occlusal-HP, Duo-film). The vehicle dries rapidly to prevent spread of the acid onto surrounding skin. The patient is instructed to apply the medication to the wart at bedtime and to cover the area with thick tape. Superficial necrotic tissue should be pared daily, with either a pumice stone or, for thick palmar or plantar warts, a callus grater. The latter warts often require a stronger acid, such as a 40% salicylic acid plaster. These products can be bought over the counter (Mediplast and Duofilm patches), but patients need instruction in application. A piece of plaster is cut to match the size of the wart, and its adhesive, medicated side is applied to the wart and held in place with tape. The plaster is changed every 24 hours and the macerated wart pared daily, as previously described.

Flat warts are often treated successfully with topical adapalene (Differin), tretinoin (Retin-A), or imiquimod (Aldara, Zyclara; see later discussion), applied nightly to the entire affected area. In this situation, these products probably act as *peeling* agents. Painful irritation may occur, necessitating less frequent use.

These home acid therapies usually require at least 1 month of continuous use to be effective. If no progress has been made after several months, then other treatments should be considered. For deeply seeded warts, paring followed by a combination of acid and cryotherapy usually provides successful treatment. Caustic acids such as trichloroacetic acid at concentrations of 30% to 100% are reserved for office treatment of palmar or plantar warts. These acids must be carefully applied because they can cause destruction of normal tissue as well. Cantharidin is a protein phosphatase inhibitor produced by the Spanish fly, *Lytta vesicatoria*. It penetrates the epidermis and causes acantholysis, resulting in vesiculation and destruction of infected keratinocytes. Cantharidin can be used for almost all nongenital warts. Reapplication may be required at 1- to 3-week intervals. It has the advantage of being painless when initially applied and causes little risk for scarring. Occasionally, a ring wart will develop at the edge of the treated site.

All of these treatments are nonspecific, and none are foolproof. In some instances, different modalities are used in sequence. Although warts commonly regress spontaneously, the time required for this varies considerably. In some patients, therapy may only serve to appease the patient while nature takes its course. In other patients, the destructive techniques may initiate an

**Figure 345-3** Condylomata acuminata appear as skin-colored papules and plaques.

inflammatory reaction, exposing the wart viral antigen to the body's immune system, which finally rejects the wart. This reaction may explain the occasionally observed phenomenon that by treating the mother wart, the baby wart goes away. In any event, whenever warts are treated, the pediatrician must consider the risk-benefit ratio of therapy. Accordingly, surgical excision is usually discouraged, and radiotherapy is contraindicated.

### Immunotherapy

Imiquimod cream (in 5% [Aldara] or 3.75% [Zyclara] concentrations) is an immunomodulator that augments cellular immunity by inducing a variety of cytokines. It can be self-administered daily or every other day and should be left on overnight. Controlled, multicenter trials have evaluated its role in treating genital warts, but trials will soon be underway for common warts as well. In addition, some smaller studies and case reports are already suggesting its potential as an alternative treatment, either alone or in combination with other modalities, such as cryotherapy and salicylic acid. Imiquimod's mechanism of action may also make it especially useful in treating nongenital warts in immunosuppressed patients.

Sensitization to squaric acid is another therapeutic option. It is available as squaric acid dibutylester in acetone (SADBE) in concentrations of 0.5% and 1% for home use, and 2% for office use. The solution is first applied in the office to a small area (usually the inner arm), usually causing no reaction, or occasional mild redness. Then 2 weeks later, it can be applied at home with a cotton-tipped applicator to the lesions. It can be applied 3 times a week, then gradually increased by 1 night a week on a weekly basis as tolerated. Usually improvement is seen by 3 weeks and clearance by 7 weeks. Complete clearance rates range from 58% with home use, to 68% with in-office use, to 86.2% with in-office application after 70% salicylic acid in petrolatum use at home before therapy. This treatment is absolutely contraindicated in vitiligo because it can exacerbate the associated depigmentation.

Intralesional therapy involving sensitization to antigens, such as *Candida*, mumps, or *Trichophyton*, is another technique used by dermatologists when topical therapies fail. Studies have demonstrated response rates ranging from 54% to 87% in treated warts and 34% to 78% in untreated, distant warts.

### Electrodesiccation and Laser Therapy

Electrodesiccation of a wart can be preceded or followed by curettage. One advantage of this technique is that the patient leaves the office without visible evidence of the wart, although the cure rate is probably no higher than with cryotherapy. The disadvantages are that (1) the procedure requires local anesthesia, and (2) scarring is more likely. The carbon dioxide laser can be used to destroy large or refractory warts, but the risk for scarring is significant. The pulsed dye laser, which destroys the vascular component of the wart, may become another alternative, with less risk for scarring. It is used for some recalcitrant warts, particularly in palmar, plantar, periungual, and anogenital areas.

### Other Treatments

A recent study showed that duct tape occlusion therapy was significantly more effective than cryotherapy in treating nongenital warts.

The efficacy of oral cimetidine in the treatment of warts is still controversial. It may be useful in the treatment of flat warts. Use of oral cimetidine in other types of warts is under investigation.

Zinc can function as an immunomodulator, and its deficiency causes lymphopenia. Two studies in zinc-deficient patients with warts suggest that oral zinc sulfate may be an effective, inexpensive, and painless therapeutic alternative. Additional controlled studies in nondeficient patients are needed to confirm its therapeutic efficacy.

Phototherapy uses topical photosensitizing agents, most commonly 5-aminolevulinic acid (ALA), followed by exposure to light, which causes accumulated porphyrins to unleash a photooxidation cascade that destroys treated cells. In randomized controlled trials investigating it for recalcitrant palmar and plantar warts, cure rates ranged from 56% to 75%. It also demonstrated 94.4% clearance of facial warts in one study.

### Treatment of Genital Warts

Although condylomata in children are usually asymptomatic, they may be treated to curtail their spread and allay parental concerns. Some forms of therapy may be painful, and recurrence rates may be as high as 50%. Weighing the risks versus the benefits is wise before treating genital warts in children.

Two therapeutic options for condyloma have been approved by the FDA in adults, and case reports with children have shown promise—imiquimod (described previously) and podophyllotoxin. Podophyllin is derived from the mayapple plant and is available in 10% to 25% solutions in alcohol or benzoin. It is exclusively for office use. Podophyllin is painless when applied but can be toxic if used over large areas. It must be washed off within 6 to 8 hours of application. Podophyllin is also marketed as purified 0.5% podophyllotoxin (Condylox) solution or gel. Podophyllotoxin has also been shown to be effective in case reports involving children and infants. It is available for home use but can be very irritating for some patients.

A third therapeutic option, sinecatechins, has been approved by the FDA for adults, but its use in children has not yet been reported in the literature. Sinecatechins is a partially purified fraction of the water extract of green tea leaves from *Camellia sinensis* (L.) O Kuntze and is a mixture of catechins and other green tea components; it is thought to have antioxidant, antiviral, and antitumour activity against warts. It is marketed as an ointment (Veregen) that should be applied 3 times a day for up to 16 weeks. Other options for treatment of condylomata include cryotherapy, lasers, caustic acids, and cimetidine.

### Complications

The major complications of warts are those caused by overzealous therapy, resulting in short-term discomfort or scarring. The annoyance of the presence of a wart, which is usually temporary, must be balanced

against the inconvenience of a scar, which is usually lifelong, may be unsightly, and is sometimes tender, particularly if present on a pressure-bearing surface such as the sole of the foot.

### Prognosis

Most warts eventually involute spontaneously, probably through immunologic rejection. Because the time required for involution varies greatly, predicting when it might occur for an individual patient is impossible. The goal of therapy, then, is to shorten the time required for the wart to disappear. The therapies outlined in this chapter result in clearing in most cases; but patients who have resistant, persistent warts will continue to be plagued by them. More specific therapy is needed for these patients especially, and these patients may benefit from an evaluation by a dermatologist.

## MOLLUSCUM CONTAGIOSUM

Since the eradication of smallpox, molluscum contagiosum is the only poxvirus infection that specifically affects humans. Similar to warts, molluscum lesions are virally induced tumors of the skin. In children, molluscum contagiosum is a common, benign, self-limited process.

### Etiology

Molluscum contagiosum is caused by molluscum contagiosum virus (MCV), a large double-stranded DNA virus of the *Molluscipoxvirus* genus. Four subtypes of the virus have been identified. Although most cases of infection are caused by the first subtype, MCV-1, the subtypes are clinically indistinguishable.

### Epidemiologic Features

In the United States, fewer than 5% of children demonstrate MCV infection, with approximately 80% of cases occurring in children younger than 8 years. Gender distribution is equal. It is spread by contact, through skin-to-skin contact (eg, certain sports, sexual activity), fomites (eg, sponges, towels, beauty parlors, heated public pools and baths), or autoinoculation. Of note, patients with impaired cell-mediated immunity have increased incidence and severity. Examples include HIV-positive patients (although incidence has been somewhat controlled with the success of highly active antiretroviral therapy [HAART]), patients with atopic dermatitis, and patients receiving immunosuppressants.

### Physical Findings

The lesions of molluscum contagiosum are discrete, dome-shaped, umbilicated, waxy papules, and their color can be skin colored, pink, or white. Their translucence may cause them to resemble vesicles. The lesions may also resemble milia or skin tags. Their diameter usually does not exceed 5 mm, although they can sometimes be as wide as 15 mm (ie, giant molluscum). Lesions may occur anywhere on the body, although the most common locations are the axilla, sides of the trunk, lower abdomen, thighs, and face. Although genital molluscum contagiosum in young children do not necessarily indicate sexual abuse, it should be considered.

### Laboratory Findings

Molluscum contagiosum is usually diagnosed clinically. If the diagnosis is unclear, then a skin biopsy can confirm it.

### Differential Diagnosis

The diagnosis of molluscum contagiosum is generally straightforward. However, it may occasionally be mistaken for verrucae, varicella, folliculitis, furunculitis, milia, juvenile xanthogranuloma, spitz nevi, and skin tags.

### Management

#### Active Nonintervention

Some lesions resolve spontaneously within a few weeks, although the average lesion takes 2 to 3 years to clear, with some lesions taking up to 5 years. For most active children, avoiding situations that promote spread and proliferation is sufficient. Behaviors to avoid include excoriating lesions, walking barefoot in public places, and sharing personal items such as towels and sponges. However, if lesions are numerous or persistent, or if new lesions continue to appear, then therapeutic intervention can be helpful. In the case of periocular molluscum contagiosum, the risk for iatrogenic injury justifies active nonintervention unless symptomatic conjunctivitis is present, when surgical removal under general anesthesia is merited.

#### Tretinoin

The ability of topical tretinoin to induce local inflammation has also been helpful in treating molluscum contagiosum, although controlled trials are needed to confirm its efficacy. It can be applied daily for 2 to 3 months, and it can be used safely on the face and other sensitive areas. Side effects are usually mild and include site irritation, dryness, and photosensitivity; thus, patients should be advised to wear sunscreen and limit sun exposure while using tretinoin.

#### Duct Tape

Duct tape can be used for recalcitrant molluscum contagiosum. It can be cut to the size of each lesion and applied (and reapplied if needed) until all lesions have cleared. Duct tape is an attractive treatment option because it is affordable, available over the counter, nondestructive, and painless (or minimally painful), and it can be used at home, reducing the need for office visits. Controlled studies comparing it with conventional treatments are needed to further establish its efficacy.

#### Cantharidin

Cantharidin, a vesiculating agent derived from the Spanish fly, is a helpful in-office treatment for molluscum contagiosum lesions. Although it has not been approved by the FDA, cantharidin has been recommended by the FDA's Pharmacy Compounding Advisory Committee for inclusion as a compounded medication to be used in physicians' offices since 1998. Local pharmacies may compound the 0.7% solution, or it can be obtained in compounded form by several American and Canadian manufacturers. Cantharidin is administered in the office using the blunt wooden end of a cotton-tipped swab and applied sparingly to the lesions. It should be rinsed

off with liberal amounts of water in 4 to 6 hours, or sooner if the patient complains of pain or if vesiculation occurs. Cantharidin may be reapplied in 2 to 4 weeks. In a recent study involving 300 children with molluscum contagiosum treated with cantharidin, 90% had clearance of their lesions after an average of 2 treatment visits, and an additional 8% had improvement of their lesions. The most common side effects were related to site irritation. Experts have suggested that occlusion with translucent tape 5 minutes after cantharidin application can enhance clearance of persistent lesions; the tape can be removed when blistering or soreness develops. On rare occasions, patients may have an exaggerated response with large blister formation. Some experts recommend that every patient have a test dose of the agent to a few lesions and wait up to a week to assess the response before proceeding to treat extensive areas. Some patients never get blisters—just irritation and erythema. Because cantharidin can cause hyperpigmentation or hypopigmentation, it is not recommended for use on facial lesions.

### **Podophyllin**

Podophyllin 25% solution acts as a keratolytic. It is applied in the office sparingly to lesions and should be washed off within the first 6 hours of treatment to minimize site irritation. Podophyllin can be reapplied weekly for up to 4 weeks. Controlled studies are needed to establish its efficacy in comparison to other treatment modalities.

### **Cryotherapy**

A light freeze with liquid nitrogen can be helpful in treating older children with a small number of large lesions. Treatment may need to be repeated in 2 to 4 weeks.

### **Curettage or Needle Extraction**

Curettage or needle extraction done with local anesthesia is an older technique that may be used for larger lesions that do not respond to topical treatments, but are best reserved for older children who can better tolerate these procedures.

### **Pulsed Dye Laser**

Although very effective and generally well tolerated, the use of pulsed dye laser is limited by its high cost, the need for special equipment, and the risk for transient hyperpigmentation. Pulsed dye laser remains a third-line treatment for recalcitrant lesions.

### **Other Treatments**

Trichloroacetic acid (TCA) solution in 20% to 35% concentration is another destructive treatment technique. Unlike cantharidin, it does not cause significant irritation or dyspigmentation, making it ideal for facial lesions. Using the pointed edge of a cotton-tipped applicator, it is repeatedly applied to the center of a lesion until a white frost appears. It can induce a mild stinging sensation but is otherwise well tolerated.

Intralesional immunotherapy with *Candida* antigen is another technique performed by dermatologists

for lesions resistant to topical therapy. Studies have demonstrated complete clearance rates of about 55% and partial clearance rates ranging from 28% to 38%.

Cimetidine is an histamine-2 antihistamine that is thought to stimulate the cell-mediated immune response and remains an adjunctive therapy. Controlled studies are needed to verify its efficacy.

In patients with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS), MCV lesions do not usually resolve until CD4<sup>+</sup> lymphocyte counts remain consistently above 200 cells/mm<sup>3</sup>. Since the introduction of HAART, there are significantly fewer cases of AIDS-related MCV. If lesions are resistant to HAART, cidofovir is an option. Cidofovir is a nucleotide analog of deoxycytidine monophosphate with activity against MCV. Although both systemic and topical forms are effective against MCV, topical cidofovir is preferable because it does not have the nephrotoxicity seen in its systemic form. Topical cidofovir 1% or 3% should be combined with a vehicle containing propylene glycol and applied once a day, 5 days a week, for 8 weeks. For maximal efficacy on nonfacial lesions, it should be applied under occlusion for at least 12 hours. Side effects include superficial scars, post-inflammatory hypopigmentation and hyperpigmentation, and varioliform scars after large lesions. No systemic adverse effects have been reported.

Many homeopathic remedies, such as Natrum Sulphuricum, sulfur, Natrum Muriaticum, and thuja ointment and cream, have been advertised for the treatment of MCV, but no controlled studies have been published in the Western medical literature to confirm their safety and efficacy.

### **Complications**

Molluscum contagiosum virus infection is considered a benign condition. During resolution, mild erythema and irritation can occur as part of the local cellular immune response. These signs should not be confused with those of bacterial superinfection, which can occur secondary to excoriation and resulting impetiginization. If significant tenderness, crusting, or purulent drainage occurs, then treatment with topical or oral antibiotics is warranted.

Atopic individuals frequently develop patches of eczema (molluscum dermatitis) in the area of the lesions, presumed to be a result of their immune response to the virus or repeated excoriation of the lesions.

### **Prognosis**

Although most healthy children do not experience recurrences of MCV infection, extensive molluscum infections can occur in immunocompromised individuals, especially patients with HIV or AIDS.

### **WHEN TO REFER**

- Warts or molluscum contagiosum in the perineal or perianal area in a child
- Unresponsive/persistent or extensive warts or molluscum contagiosum

## Chapter 346

# VITAMIN D INADEQUACY

Adekunle Dawodu, MBBS; Carol L. Wagner, MD

## OVERVIEW

Vitamin D and its active metabolites (primarily D<sub>3</sub>), in addition to calcium and bone metabolism, have been shown to mediate effects on cellular metabolism in almost every organ system in the body, including a role in upregulating innate immune and downregulating autoimmune functions. While evidence continues to mount from epidemiologic studies regarding vitamin D's role in long-latency diseases such as cancers, and autoimmune and other inflammatory diseases, there is much controversy surrounding what constitutes vitamin D sufficiency and insufficiency, and what is an adequate intake throughout the life span. The data are insufficient for a determination of what is an optimal vitamin D concentration within the various compartments of the body although, emerging evidence suggests that what once was thought adequate—the amount of vitamin D necessary to prevent rickets, whether derived from the sun, diet, or supplement—is not enough to optimize immune function. How then can a physician determine if a growing child is receiving adequate vitamin D? Does the source of vitamin D matter—is sunlight-derived vitamin D superior to that from dietary sources? What about toxicity? For some of these questions, there are answers; for others, the answers change as our understanding of the cellular and molecular functions of vitamin D improves.

## WHAT IS VITAMIN D?

Vitamin D is a hormone that is either synthesized by the skin (vitamin D<sub>3</sub> or cholecalciferol) or derived from the diet (found in fish, eggs, animal organs such as

liver, or plants). Vitamin D synthesis by the skin accounts for more than 90% of the vitamin D stores in most people. Vitamin D obtained from foods or as a supplement is absorbed from the small intestine into the bloodstream and carried to the liver, where it is converted to 25(OH)D. Within the body, vitamin D synthesized from the skin seems interchangeable with that obtained from the diet. The half-life of vitamin D is 12 to 24 hours and that of the active form of the hormone, 1,25(OH)<sub>2</sub>D is 4 to 6 hours. In comparison, the half-life of 25(OH)D is approximately 3 weeks, which makes it the best indicator of vitamin D status.

Whereas excessive exposure to sunlight does not further increase vitamin D production to cause toxicity, the same is not true for intestinal absorption of the dietary vitamin D. With ongoing sunlight exposure, previtamin D<sub>3</sub> is degraded into inert products with no effects on calcium metabolism. With oral vitamin D, there is the potential for toxicity, because vitamin D is a fat-soluble compound and is stored in the liver and fat. There are numerous cases of vitamin D toxicity described when individuals received thousands to hundreds of thousands IU of vitamin D per day. The Institute of Medicine (IOM) states in a recent report that in infants younger than 6 months old, up to 1,000 IU/day and in those aged 6 to 12 months 1,500 IU/day vitamin D are safe. In adults, that level is 4,000 IU/day. More recent studies suggest that for adults, the upper limit of safety is higher than 4,000 IU/day. The upper limit of safety for older children and adolescents remains unclear.

## VITAMIN D INADEQUACY: DIFFERENTIATING VITAMIN D DEFICIENCY FROM INSUFFICIENCY

There is excellent evidence that a total circulating 25(OH)D level greater than 10 ng/mL (25 nmol/L) will prevent rickets, but recent global review indicates that the threshold of serum 25(OH)D for developing rickets may be higher. If the goal, for example, is to achieve a circulating 25(OH)D concentration that is associated with optimal immune function, then that goal is unclear. The needs of the growing child are even less clear. There is mounting evidence that better health outcomes, particularly in adults, are associated with 25(OH)D levels greater than 20 ng/mL (>50 nmol/L) and still better outcomes at levels greater than 32 ng/mL (80 nmol/L); whether or not the same holds true across the life span remains uncertain. No evidence to date suggests that when compared to adults, children have different metabolic pathways or thresholds for deficiency. Indicators of overt disease such as rickets or osteomalacia are seen in both adults and children at serum 25(OH)D levels below 10 to 12 ng/mL (25–30 nmol/L). Across the lifespan, parathyroid hormone (PTH) levels seem to increase when circulating 25(OH)D concentrations fall below 20 ng/mL (50 nmol/L). With children, an increase in alkaline phosphatase (ALP) also accompanies worsening vitamin D deficiency. The American Academy of Pediatrics (AAP) considers serum 25(OH)D less than 20 ng/mL (50 nmol/L) as insufficiency, and IOM considers values below 12 ng/mL (30 nmol/L) associated with rickets as deficiency.

### BOX 346-1 Causes of Vitamin D Deficiency and Insufficiency

- The substrate supply is limited or has become limited by an ongoing lack of sunlight exposure
- A diminished dietary supply of vitamin D (particularly in exclusively breastfed infant)
- Enhanced metabolic processing of 25(OH)D to more biologically inert vitamin D moieties
- Malabsorption of dietary vitamin D

## ETIOLOGY AND INCIDENCE OF VITAMIN D DEFICIENCY AND INSUFFICIENCY

The causes of vitamin D deficiency and insufficiency are listed in Box 346-1. There is a seasonal variation in the presentation of the disease—the risk is greater in late winter and early spring than summer or fall. Those who have darker pigmentation are at greatest risk because their melanocytes filter the very UVB necessary for the conversion of 7-dehydrocholesterol to vitamin D<sub>3</sub> in the skin. It is also known that those who have higher body mass indices are at greater risk of vitamin D deficiency. Others at risk for vitamin D deficiency include those with fat malabsorption, most notably children with cystic fibrosis; they cannot absorb vitamin D well from the gut, because it is fat-soluble. Children who take antiepilepsy medications such as phenobarbital and phenytoin, which can increase the liver's P450 conversion of 25(OH)D to inactive compounds, can lower serum 25(OH)D concentrations and reduce calcium absorption.

The 2001–2006 NHANES provides the most recent data on the vitamin D nutritional status of 4,558 US children aged 1 to 11 years. Overall, 1% of the children had serum 25(OH)D levels below 10 ng/mL (<25 nmol/L), 18% had levels below 20 ng/mL (<50 nmol/L) and 95% had levels below 30 ng/mL (<75 nmol/L). The prevalence of vitamin D deficiency and insufficiency is higher in non-Hispanic black and Hispanic than non-Hispanic white children. In a recent study in South Carolina involving pregnant women, more than 75% of African American women, 50% of Hispanic women, and 12% of Caucasian women were vitamin D deficient as defined by circulating 25(OH)D concentrations below 20 ng/mL (50 nmol/L). If the mother is deficient, her developing fetus—who derives vitamin D stores from the mother—is deficient. Neonatal 25(OH)D concentrations in the blood are 0.6 to 0.7 that of the mother, so vitamin D must be supplied soon after birth. In a study of neonates and their mothers in the Netherlands, Dijkstra and colleagues reported a significant difference in the prevalence of vitamin D deficiency [25(OH)D <10 ng/mL (<25 nmol/L)] between newborns of mothers with either dark skin or concealing clothing (risk group) or light skin (control group) (63.3% vs 15.8%;  $p < 0.001$ ). The situation becomes more complicated if the newborn is breastfeeding, because most newborns have little direct sunlight exposure and depend solely on the

lactating mother for their vitamin D. If the lactating mother is deficient in vitamin D, then her breast milk is deficient, with diminished vitamin D ingested by her breastfeeding infant.

## WHAT OCCURS DURING VITAMIN D DEFICIENCY?

When 25(OH)D is less than 20 ng/mL (50 nmol/L), net intestinal calcium absorption is decreased to 10% to 15%, and there is a decrease in the total maximal reabsorption of phosphate. Low ionized calcium levels stimulate PTH secretion, which leads to an increase in calcium reabsorption in renal tubules and an increase in 1 $\alpha$ -hydroxylase activity that has a direct effect on 1,25(OH)<sub>2</sub>D synthesis. Increased PTH leads to renal tubular reabsorption of calcium at the expense of phosphorus, which is lost in the urine. Sustained decreased levels of phosphorus initially and then accompanied by calcium loss lead to a decrease in the calcium and phosphorus product necessary for ongoing bone mineralization resulting in decreased bone mineralization. At the cellular level, low phosphorus levels are associated with failure or delay of osteoid calcification, referred to as osteopenia in mature bones or rickets in immature bones (see section on vitamin D deficiency rickets).

The effect of vitamin D deficiency on other systems besides bone and calcium are just beginning to be understood. The association of respiratory infections in those children with rickets well described by scientists at the turn of the 20th century went largely unnoticed until more recent laboratory molecular techniques allowed experiments to be performed that linked vitamin D with both innate and adaptive immune function. These findings in the laboratory, together with a plethora of epidemiologic studies, suggest that vitamin D plays a significant role in maintaining health not only in the short term (eg, reducing the risk of acute respiratory infections) but also in the long term, with such long-latency diseases as diabetes, multiple sclerosis, and certain cancers. Childhood diabetes has been associated with the lack of vitamin D supplementation, but again, the optimal blood concentration of 25(OH)D remains uncertain. Future research is needed to determine if these effects are through the direct effects of vitamin D and its metabolites, or through a cascade of events initiated or circumvented by vitamin D.

## CLINICAL FEATURES OF VITAMIN D DEFICIENCY RICKETS

The clinical presentation of overt vitamin D deficiency is variable and depends on the duration and age at presentation. Although rare, profound maternal vitamin D deficiency during pregnancy could result in congenital rickets. Newborns present with respiratory distress, muscle weakness, wide anterior fontanel, craniotabes, intrauterine growth restriction and hypocalcemia, and in some cases, hypocalcemic seizures. Overt vitamin D deficiency in infancy has skeletal and nonskeletal clinical presentations.

**Table 346-1** Common Clinical Features of Rickets in the United States (1986–2003)

FEATURES	NUMBER OF PATIENTS ASSESSED	% WITH ABNORMAL FINDINGS
Skeletal deformities	147	74
Poor growth	142	60
• Length for age (<5th percentile)	91	44
• Weight for age (<5th percentile)		
Delayed motor development	64	14
Hypocalcemic seizures	121	12
Radiologic evidence of rickets	159	98

Adapted from Weisberg P, Scanlon KS, Li R, Cogswell ME. Nutritional rickets among children in the United States: review of cases reported between 1986 and 2003. *Am J Clin Nutr*. 2004;80(6 suppl):1697S–1705S.

Hypocalcemia is the typical nonskeletal presentation in early infancy. There are reported cases of seizures and tetany (both of which typically occur in association with hypocalcemia) in early infancy and adolescence, which are periods of increased growth velocity. With rapid growth, the increased demand for calcium cannot be met in a timely fashion, and the patient may present with hypocalcemia even before bone demineralization or rickets secondary to profound vitamin D deficiency is observed.

In later infancy and early childhood, the most common presentations are skeletal abnormalities, delayed motor development, suboptimal physical growth, and muscle weakness and myalgias. In 166 cases of rickets reported in the United States between 1986 and 2003, the most common features were skeletal abnormalities, suboptimal growth, and radiographic changes of rickets (see Table 346-1). The skeletal abnormalities associated with rickets typically include widening of the wrists and the ankles, bow legs (genu varum), abnormal gait, prominence of costochondral junctions (rachitic rosary), and skull abnormalities such as delayed closure of fontanels, craniotabes, and frontal bossing. Rarely, dilated cardiomyopathy with heart failure may be associated with hypocalcemia, and the infants usually respond to vitamin D and calcium therapy.

Children with vitamin D deficiency are reported to be at increased risk of acute lower respiratory tract infections (ALRTIs). A case control study from Ethiopia found a 13-fold higher incidence of rickets among children with pneumonia than among the controls. In another case control study from India, severe ALRTI is 11 times more common in infants with 25(OH)D levels below 10 ng/mL (<25 nmol/L) than those with levels above 10 ng/mL (25 nmol/L). An observational study from Canada found that children with vitamin D deficiency [defined as serum 25(OH)D <20 ng/mL (<50 nmol/L)] were 8 times more likely to require pediatric intensive care than general ward admission. Such aspects of the disease are consistent with vitamin D's putative role in maintaining innate and adaptive immune functions. The clinical presentations and features by age at presentation are summarized in Box 346-2.

Rickets is often diagnosed by radiologic and laboratory findings. The radiologic features include irregular bone mineralization, cortical thinning of

### BOX 346-2 Clinical Presentations of Vitamin D Deficiency by Age at Presentation

#### AT BIRTH

- Intrauterine growth restriction
- Hypocalcemia
- Congenital rickets
- Neonatal seizures resulting from hypocalcemia

#### EARLY INFANCY

- Hypocalcemia
- Hypocalcemic seizures or tetany
- Craniotabes

#### LATE INFANCY AND CHILDHOOD

- Delayed physical growth (short stature)
- Delayed gross motor development
- Inability to bear weight on legs or walk
- Waddling gait
- Muscle weakness
- Frontal bossing
- Delayed closure of fontanelle
- Swelling of wrists, ankles, or knees
- Rachitic rosary (enlargement of costochondral junctions)
- Bowing of lower legs
- "Pigeon chest" deformity
- Rarely, stridor, cardiomyopathy, and fracture
- Increased risk of acute lower respiratory tract infection

long bones, metaphyseal widening, fraying and cupping, and underdevelopment of the epiphysis. The typical radiologic changes in rickets are shown in Figure 346-1.

Common laboratory findings in vitamin D deficiency rickets are hypophosphatemia, varying degrees of hypocalcemia, elevated serum ALP and PTH levels. Other biochemical abnormalities include generalized aminoaciduria and reduced urinary calcium excretion. The diagnosis of vitamin D deficiency rickets is confirmed by measuring serum 25(OH)D concentration. Although there is no absolute threshold

level of 25(OH)D for development of vitamin D deficient rickets, the serum 25(OH)D level is usually below 20 ng/mL (50 nmol/L) and values below 12 ng/mL (30 nmol/L) are very common. In a recent study from the United States of 47 cases of rickets with documented serum 25(OH)D levels, 37 (79%) had levels lower than 20 ng/mL (50 nmol/L) and 30% of these were lower than 5 ng/mL (12.5 nmol/L). In another recent study of 38 cases of rickets from the United Arab Emirates, 35 (92%) had serum 25(OH)D levels lower than 10 ng/mL (25 nmol/L).

### DIFFERENTIAL DIAGNOSIS

In addition to vitamin D deficiency rickets, physicians should be alert to other causes of childhood rickets, including phosphate deficiency caused by abnormal phosphate metabolism, calcium deficiency, 1 $\alpha$ -hydroxylation defect (type 1 vitamin D-dependent rickets), impaired biological response to 1,25-dihydroxy vitamin D (vitamin D-resistant rickets), renal tubular acidosis, and renal osteodystrophy. The clinical features of these various conditions are similar, but the medical history,

**Figure 346-1** Untreated vitamin D deficiency rickets. The figure demonstrates widening of the epiphyseal plate, underdevelopment of the epiphysis, splaying, irregularity (fraying), and cupping of the metaphysis.

biochemical changes, and clinical response to vitamin D supplementation are helpful to distinguish among them. These cases would require specialist referrals. The biochemical parameters: serum calcium (Ca), phosphorous (P), PTH, 25(OH)D, 1,25(OH)<sub>2</sub>D, and urinary calcium in the different forms of rickets are summarized in Table 346-2.

### TREATMENT AND PREVENTION

#### When to Check Levels

Pediatricians should be aware that vitamin D insufficiency and deficiency are common in children. This justifies a low threshold for diagnosing vitamin D deficiency, especially in winter months and in those at high risk, which includes rapid growth, dark-skinned breastfed infants without vitamin D supplementation, children on chronic anticonvulsant therapy, and children with chronic disorders associated with malabsorption, such as cystic fibrosis and inflammatory bowel disease. Furthermore, a study from the United Arab Emirates suggests that maternal vitamin D deficiency is more common in infants with rickets than in those without rickets and additionally suggests that maternal vitamin D deficiency should prompt suspicion of subclinical vitamin D deficiency in the infant. The suspicion of vitamin D deficiency should be confirmed by measurement of serum 25(OH)D. Measurement of serum 25(OH)D levels is also indicated when a child presents with clinical manifestations of rickets. In cases of unexplained fractures in children, it is imperative to check serum Ca, P, ALP, and 25(OH)D levels to rule out organic causes as the etiology of the fracture(s).

#### Treatment

Vitamin D and calcium therapy is necessary for infants and children who manifest clinical features of hypocalcemia as a result of vitamin D deficiency or who present with rickets and have serum 25(OH)D levels that are in the deficient range. In active rickets, vitamin D supplementation in a total cumulative dose of 200,000 to 600,000 IU is required to replenish vitamin D stores. Three different dosing regimens advocated are as follows:

1. Daily oral administration of 2,000 to 5,000 IU vitamin D for 2 to 3 months to normalize the 25(OH)D levels and replenish vitamin D stores;

**Table 346-2** Biochemical Findings in Different Forms of Rickets

TYPE OF RICKETS	CA	P	PTH	25(OH)D	1,25 (OH) <sub>2</sub> D	URINARY CA
Vitamin D deficiency	LOW/NRML	LOW	HIGH	VLOW	LOW/NRML	LOW
Calcium deficiency	LOW	LOW	HIGH	NRML	HIGH	LOW
Hypophosphatemia	NRML	LOW	NRML	NRML	LOW/NRML	NRML
Vitamin D metabolism defect	LOW	LOW	HIGH	NRML	LOW	LOW
• Type 1 vitamin D dependent						
Vitamin D receptor defect	LOW	LOW	HIGH	NRML/HIGH	VHIGH	LOW
• Vitamin D resistant						
Renal osteodystrophy	LOW	HIGH	HIGH	LOW	LOW	LOW

NRML, normal range; VHIGH, markedly increased; VLOW, markedly decreased.

- 2. Weekly 50,000 IU vitamin D for 8 weeks or until the serum 25(OH)D level is normalized;
- 3. Single or divided dose of 200,000 to 400,000 IU vitamin D (Stoss therapy) has been suggested when lack of compliance is a concern. Close monitoring is required with this regimen in view of the concern for hypercalcemia.

Serum calcium, phosphorous, and ALP should be monitored in the first month. Serum 25(OH)D levels should be monitored during the first 3 months and at 3-month intervals with calcium, phosphorous, and ALP to achieve a normal calcium level and serum 25(OH)D above 20 ng/mL (50 nmol/L). After the serum calcium and vitamin D levels have returned to normal, the vitamin D intake will be reduced to a minimum of 400 IU daily as a maintenance dose with adequate calcium intake.

Hypocalcemia should also be treated with calcium supplements. Treatment of symptomatic hypocalcemia consists of administering a 10% calcium gluconate solution at 10 to 20 mg of elemental calcium per kilogram intravenously slowly over 5 to 10 minutes. This is sufficient to treat symptomatic hypocalcemia, but repeated doses may be necessary. Oral calcium supplements should be continued until serum calcium levels return to normal.

A biochemical monitoring plan during treatment of vitamin D deficiency rickets includes serum Ca, P, ALP (at 1 month); serum Ca, P, ALP and 25(OH)D (at 3 months); and serum 25(OH)D levels at 6 months and at 1 year. A radiological evaluation should be repeated at 3 months and after 1 year to monitor healing. Skeletal abnormalities usually take much longer than biochemical abnormalities to return to normal.

Prevention of Vitamin D Deficiency

Given the growing knowledge about the effects of vitamin D not only on bone mineral metabolism, but

also on immune function and in preventing various kinds of cancer and autoimmune diseases, a low threshold for avoiding vitamin D insufficiency in infants and children is recommended. Infants who are at high risk of vitamin D insufficiency, particularly breast-fed infants or formula-fed infants whose vitamin D intake is less than 400 IU daily, should be given adequate vitamin D supplementation to ensure vitamin D sufficiency. The American Academy of Pediatrics (AAP) recommends that physicians caring for children should ensure that infants and children achieve a minimum of 400 IU of vitamin D intake daily (note that the Recent IOM report suggests a 600 IU RDA) either through vitamin D supplements or from food fortification. Higher doses of vitamin D supplements may be required in other high-risk infants—including those with fat malabsorption and those on anticonvulsant medications—to ensure vitamin D sufficiency.

VITAMIN D PREPARATIONS AVAILABLE FOR INFANTS AND CHILDREN

During the past decade, there has been an increase in the types of vitamin D supplements available to the physician and to the public. The most widely used form of vitamin D supplementation in children continues to be as part of a multivitamin preparation, which typically contains 400 IU per mL, either as a liquid preparation or in the form of a chewable vitamin. Vitamin D-only preparations are now available, some of which are summarized in Table 346-3, adapted from the 2008 AAP statement.

The main concern when dosing any vitamin or medication is the correct dispensing of the vitamin or drug. The US Food and Drug Administration issued a warning regarding the use of vitamin D-only preparations and the potential for overdosing.

The IOM 2010 report deemed 1,000 IU per day as the upper limit of safety for infants 0 to 6 months old,

Table 346-3 Vitamin D Preparations Available for Infants and Children	
PREPARATION	DOSAGE
Baby Ddrops The Ddrops Company Toronto, Canada (distributed in United States through Carlson Labs)	1 drop gives 400 IU Coconut and palm oil preparation Also comes in 2,000 IU/drop preparation 5-year shelf life
Bio-D-Mulsion Biotics Research Laboratory Rosenberg, Texas	1 drop gives 400 IU Corn oil preparation Also comes in 2,000 IU/drop preparation <sup>a</sup> 1-year shelf life
Just D Sunlight Vitamins, Inc.	1 mL gives 400 IU Corn oil preparation
Carlson Laboratories Arlington Heights, IL	1 gel cap gives 400 IU
Multivitamin preparations polyvitamins A, D, and C vitamin preparations	1 mL gives 400 IU

<sup>a</sup>Single-drop preparation may be better tolerated in patients with oral aversion issues, but proper instruction regarding administration of these drops must be given to the parents or care provider, given the increased risk of toxicity, incorrect dosing, or accidental ingestion. Adapted from Wagner CL, Greer FR. Prevention of rickets and vitamin D deficiency in infants, children, and adolescents. *Pediatrics*. 2008;122(5):1142–1152.

1,500 IU per day for infants 6 to 12 months old, 2,500 IU for toddlers 1 to 3 years old, 3,000 IU for children 4 to 8 years old, and 4,000 IU for all patients older than 8 years. Gordon and colleagues reported no safety issues in a small cohort of infants and young children ( $n = 35$ ) diagnosed with vitamin D deficiency who were at risk for osteopenia and rickets supplemented with either 2,000 IU/day vitamin D<sub>2</sub>, 2,000 IU/day vitamin D<sub>3</sub>, or 50,000 IU/week vitamin D<sub>2</sub>.

## Chapter 347

# ACUTE SURGICAL ABDOMEN

Michael D. Klein, MD

Although some abdominal pain can be evaluated in a measured way, the acute abdomen may require immediate surgical intervention. Three major diagnoses that are the most common and the most likely to cause complications if treatment is delayed must be considered. These are malrotation and midgut volvulus, which usually presents in the newborn period; intussusception, which occurs most often in children between the ages of 2 months and 2 years; and appendicitis, which is most common in children older than 5 years. Other causes of abdominal pain, some requiring immediate surgical intervention, are highlighted in Box 347-1.

### APPROACH TO THE CHILD WITH ACUTE ABDOMINAL PAIN

#### History

A complete history is important in evaluating all patients with abdominal pain. Emphasis should be placed on eliciting the nature, location, radiation, and timing of the pain and whether it is associated with physical activity or eating. Attention to symptoms of peritonitis, such as pain with cough, bumps during a car ride, or jumping, can be helpful. Most patients with an acute surgical problem will have anorexia and will usually have nausea and vomiting. Generally, their bowel habits are unchanged, or they will have constipation. Diarrhea is unusual in diseases requiring urgent operation. The pain usually precedes vomiting. Systemic symptoms such as headache and myalgia are seldom present. Pharyngitis, however, does not rule out a surgical problem. The physician must ask specifically about genitourinary tract symptoms, other illnesses, and prior operations.

#### Physical Examination

The physical examination of the abdomen is crucial. Inspection can reveal distension or a mass. Palpation should begin by gently stroking all abdominal quadrants while looking at the patient's face. With peritonitis, cutaneous hyperesthesia is often present, which can be determined by narrowing of the outer canthus of the eye (wincing). The physician should next gently percuss the entire abdomen; pain on percussion is termed rebound and indicates peritonitis, which can be localized or general. Other tests for rebound, such as pushing in on the abdomen and then suddenly letting go, are very painful and unnecessary. Gentle palpation and percussion will provide sufficient information. Percussion can also indicate gaseous distension of the intestine by the resonant note of tympany. The next step in the abdominal examination is to palpate the abdomen quadrant by quadrant, again while looking at the patient's face. The physician should

make several passes of each quadrant, with each pass being deeper, looking for a mass, tenderness, and guarding. Guarding is a specific and important sign. When the examiner pushes on a quadrant of the abdomen over the rectus muscle and it pushes back, this is known as *guarding*. Guarding cannot occur voluntarily; it indicates localized peritonitis and, most often, the need for an operation. If both the right and the left rectus push back, then this is known as *rigidity*. Rigidity indicates generalized peritonitis, but in contrast to guarding in which a single rectus muscle tenses, rigidity can be performed voluntarily.

Auscultation of the abdomen seldom offers useful information. While it is often taught that there are no bowel sounds with an ileus and high-pitched hyperactive bowel sounds are heard with obstruction, there are no data to support this distinction. The rectal examination is useful if the physician suspects a pelvic abscess or gynecologic etiologies, or if stool is needed for guaiac to screen for intussusception, but these events are unusual. The physician should assess structures or organs superior and inferior to the abdomen, because pneumonia, inguinal hernia, and testicular torsion can cause abdominal pain.

#### Evaluation

##### Laboratory Tests

Laboratory tests are helpful when the history and physical examination are not conclusive. Patients with anemia can have one of many medical conditions, such as sickle cell anemia, Henoch-Schönlein purpura, and lead toxicity. An elevated white blood cell (WBC) count is revealing. In acute appendicitis without perforation, the count is elevated from 9,000 to 14,000/mm<sup>3</sup>. If the bowel is perforated or gangrenous, or if an intra-abdominal abscess exists, then the WBC count will exceed 12,000/mm<sup>3</sup>. The urinalysis can also be revealing. A high specific gravity indicates hypovolemia. Ketones in the urine indicate significant anorexia and emesis. WBCs and bacteria in a catheterized specimen indicate a urinary tract infection. Red blood cells indicate trauma or stone. Casts may indicate glomerulonephritis that can be associated with primary peritonitis. Most patients with intussusception will have a positive stool guaiac test result.

##### Imaging

Imaging studies can also aid in diagnosis. Plain-film radiographs of the abdomen can show bowel obstruction (distended loops of bowel, air-fluid levels, absence of colonic gas), localized ileus, free air in the abdomen, scoliosis, or the impression of a mass. The chest radiograph may show free air under the diaphragm or pneumonia. Ultrasound is useful in assessing acute abdominal pain, especially in ovarian disease, but can also suggest appendicitis, intussusception, and even malrotation with midgut volvulus (reversal of the normal relationship between the superior mesenteric artery and the superior mesenteric vein). Computed tomography (CT) scan is useful in diagnosing appendicitis in patients who are obese, have sickle cell anemia, or are immunocompromised (transplant patients and those being treated for malignancy).

<sup>a</sup>The most common causes of abdominal pain.<sup>b</sup>Diagnoses considered acute surgical problems.

### Observation

In most cases of acute surgical abdomen, an operation is emergent. When considering malrotation and midgut volvulus or intussusception, immediate surgical intervention can prevent intestinal necrosis. When considering appendicitis, however, observation is a useful diagnostic aid. If a diagnosis of appendicitis cannot be made with history, physical examination, complete blood count, urinalysis, and plain films, then a period of 6 to 12 hours of observation with serial examination and a repeat WBC count may be diagnostic. Patients with appendicitis generally worsen; those without appendicitis usually improve. If observation for 6 to 12 hours does not clarify the diagnosis, then an ultrasound or a CT scan is indicated. In performing the CT scan, the patient must have a good enteric preparation with contrast, or the contrast should be instilled rectally so that it can reach the cecum. Intravenous contrast is also important because it makes the presence of inflammation much clearer.

## THREE COMMON CAUSES OF ACUTE ABDOMINAL PAIN IN CHILDREN REQUIRING URGENT INTERVENTION

### Malrotation and Midgut Volvulus

At 5 to 6 weeks of gestation, the elongating midgut pushes out into the umbilical coelom. When it returns to the abdominal cavity at 10 to 12 weeks of gestation, it rotates and fixes to the posterior abdominal wall. The duodenum returns first and is mainly retroperitoneal. It courses behind the mesenteric vessels and enters the peritoneal cavity at the duodenojejunal junction, just to the left of L2, the ligament of Treitz. The colon enters the abdomen last and rotates so that the ileocecal region is in the right lower quadrant. The right and left colon are fixed to the posterior abdominal wall by avascular attachments. Thus, the small bowel mesentery is normally fixed along a line from the ligament of Treitz in the left upper quadrant just to the left of L2 to the right lower quadrant at the right sacroiliac joint (Figure 347-1). This long fixation prevents the lengthy mass of small bowel from rotating with the superior mesenteric artery and vein as a center. This rotation, twisting, or volvulus would obstruct blood flow to the intestine and cause gangrene (Figure 347-2). If an anomaly of rotation is present, or if this long fixation does not occur, then volvulus can occur. In such anomalies of rotation and fixation (usually termed *malrotation* or *nonrotation*) the avascular adhesion of the cecum still seems to occur, although, in this case, the cecum is usually in the midabdomen and the adhesive bands (now called Ladd bands) cross the duodenum to the right upper quadrant (Figure 347-3). This obstruction of the duodenum in malrotation causes bilious emesis. The possibility of volvulus in malrotation requires urgent intervention.

Malrotation and midgut volvulus usually develop in the newborn period but can occur at any age. The characteristic symptom is bilious emesis. The occurrence of this symptom should provoke urgent gastrointestinal (GI) contrast studies. Approximately one-third of all children who have bilious emesis will

**Figure 347-1** Normal rotation and fixation of the intestine. The small-bowel mesentery is fixed to the duodenojejunal junction just to the left of L2 to the ileocecal junction at the sacroiliac joint. This arrangement prevents twisting or volvulus.

require operative intervention (although not always for malrotation and midgut volvulus). Any child with bilious emesis who has abdominal pain or tenderness should have either an operation or a contrast examination. An upper GI series to assess for the position of the ligament of Treitz is the surest way to determine malrotation. Normally, the ligament of Treitz should be at the level of the pylorus and just to the left of the midline, with the second portion of the duodenum coursing posteriorly on a lateral view. If the imager is not experienced, then a barium enema can help find the position of the cecum, which is normally below the iliac crest and to the right of the midline (although it can occasionally be in this position in malrotation). Once the diagnosis has been made in a patient with symptoms, an operation is urgently required to untwist the bowel and to perform a Ladd procedure. If the diagnosis of malrotation is serendipitous and symptoms are not present, then a Ladd procedure should be performed to decrease the likelihood of volvulus. In this procedure the Ladd bands are lysed,

**Figure 347-2** Malrotation with midgut volvulus. The small-bowel mesentery has no attachment, and, with the peristaltic motion of the intestine, the entire small bowel can twist around the axis of the superior mesenteric artery.

and the duodenum and colon are separated in an attempt to create a broad mesentery. The appendix is removed, because it will not usually be in the right lower quadrant and thus will complicate any future diagnosis of appendicitis. Hopefully some adhesions will be created to help decrease the chance of volvulus postoperatively.

### Intussusception

Intussusception occurs most commonly when the terminal ileum telescopes into the right colon. This circumstance causes not only bowel obstruction but also ischemia, because the mesenteric vessels are dragged along with the ileum. Intussusception is most likely caused by hypertrophic ileal lymphatic tissue, which acts as a lead point that is *consumed* by the more distal bowel. Other conditions associated with intussusception include Meckel diverticulum, polyps, tumors, hematoma, and vascular malformations. Most children exhibit intermittent colicky abdominal pain, although some children will be lethargic. They seem well between bouts of pain (approximately 20 minutes). Physical examination reveals a mass in the epigastrium and a feeling of emptiness in the right lower quadrant (signe de Dance). Tenderness and guarding are present as ischemia progresses. Stool is usually guaiac positive, and a *currant jelly* bloody stool may be

**Figure 347-3** Malrotation with Ladd bands. No attachment of the small-bowel mesentery to the posterior abdominal wall is seen. The avascular adhesions that would normally perform this task instead extend across the duodenum, causing an obstruction.

passed. Diagnosis is made most rapidly by ultrasound or contrast enema. Reduction of the intussusception often can be made by contrast enema using barium, nonionic contrast, or air. When contrast enema reduction fails, an operation is necessary. During the operation, the physician can usually reduce the intussusception, or a resection and anastomosis can be performed. The appendix is also removed. Recurrence occurs in 5% of cases, usually within 72 hours of the original disease. Treatment is the same as that in the initial occurrence. See Chapter 257, Gastrointestinal Obstruction, for more information.

### Appendicitis

Appendicitis (see Chapter 351, Appendicitis) is probably caused by obstruction of the lumen by feces or hypertrophic lymphatic tissue that allows stasis and bacterial multiplication to occur in the closed space. Early symptoms of appendicitis are diffuse or periumbilical abdominal pain followed by anorexia, nausea, vomiting, and localization of the pain to the right lower quadrant. Physical examination reveals a fever of up to 38.6°C (101.5°F), right lower quadrant tenderness, and guarding. The WBC count is usually elevated to 9,000 to 14,000/mm<sup>3</sup>. Symptoms usually progress over 36 hours until perforation occurs; usually diffuse peritonitis follows. After perforation, the tenderness is

no longer localized and the guarding becomes rigidity. The temperature rises above 38.6°C, and the WBC count exceeds 14,000/mm<sup>3</sup>. Abdominal radiographs may reveal scoliosis to the right, an ileus pattern, and a fecalith early on. In perforated appendicitis, the impression of a right lower quadrant soft-tissue mass may be present, as well as a gas pattern of bowel obstruction, with multiple loops of bowel with air-fluid levels. In female patients, an ultrasound can be helpful to evaluate the possibility of ovarian or tubal disease, and some experts think this evaluation is helpful in male patients to identify appendicitis. Most surgeons currently prefer an abdominal CT scan with intravenous contrast and with contrast of the GI tract in which the contrast has reached the colon when the diagnosis cannot be made clinically. Once the diagnosis of appendicitis has been made, an operation is indicated. This procedure is performed either laparoscopically or by laparotomy, whether perforation has occurred or not. Laparoscopy is especially useful when the diagnosis remains in doubt, because the entire abdomen and pelvis usually can be well visualized; it also can reduce the morbidity associated with the large incision needed in obese patients. Once the diagnosis has been made, administering analgesics and antibiotics is reasonable.

If a patient reports symptoms lasting longer than 72 hours, then the physician should consider a perforated appendicitis with abscess or phlegmon. This diagnosis is usually made by visualizing abscess or phlegmon on a CT scan. These patients can be treated with broad-spectrum intravenous antibiotics. If an abscess is present, this may be drained percutaneously. If their symptoms resolve in 2 to 3 days, these patients can then be discharged home on antibiotics. Some physicians ask patients to return in 6 to 8 weeks for interval appendectomy, which can be done laparoscopically. Little morbidity exists to an elective laparoscopic appendectomy, even after perforation. Most patients will eat on the evening of the operation and be discharged the next day. Immediate operation for a delayed presentation of perforated appendicitis can result in a very large incision and a long, complicated hospital course.

## DIFFERENTIAL DIAGNOSIS

Secondary bacterial peritonitis is usually caused by appendicitis, but it can be the result of any hollow-organ perforation. Other organs that can rupture and lead to peritonitis are the spleen and kidney, although the peritonitis and pain from these ruptured organs are likely caused by the irritation from blood and urine in the peritoneal cavity.

The second most common organ to perforate is the jejunum, as a result of blunt abdominal trauma. A radiograph of the patient's upright abdomen may not show free air, and a CT scan may show only a small amount of fluid. Persistent abdominal tenderness after blunt abdominal trauma may be the only sign of a perforated jejunum. A seat belt mark is often associated with internal injuries such as intestinal perforation. In children, a history of trauma causing such a rupture may not be obvious (a fall or wrestling match) and may be difficult to elicit, particularly if the child is injured while playing in an unsafe area and is

reluctant to admit this activity to the parents. Injury to the spleen or kidney may be related to a previously undiagnosed enlarged kidney (hydronephrosis, Wilms tumor) or spleen (mononucleosis). A perforated ulcer is rare in children and is characterized by free air on abdominal and chest radiographs. Meckel diverticulitis is less common than bleeding from a Meckel diverticulum. The signs, symptoms, and other findings are not especially different from those of appendicitis. Most foreign bodies, including open safety pins, will pass through a child's GI tract without event, but perforation can occur.

Bowel obstruction usually causes bilious emesis and abdominal pain. The abdomen is distended (unless it is a high small-bowel obstruction), and a radiograph of the upright abdomen shows distended loops of bowel with air-fluid levels and no gas in the colon or rectum. The most common cause of bowel obstruction is adhesions resulting from a previous operation; incarcerated hernia and congenital bands are other causes.

Ectopic gestation can be diagnosed with a pregnancy test or an ultrasound. Ultrasound is also important to identify gynecologic conditions such as ovarian torsion. The consideration of pelvic inflammatory disease indicates a pelvic examination, which may reveal discharge from the cervical os or cervical motion tenderness. Pain originating from testicular disease is often referred to the abdomen. Diagnosis can usually be made on physical examination. (See Chapter 190, Scrotal Swelling and Pain.)

Right upper quadrant symptoms and signs suggest gallbladder disease that can be confirmed by ultrasound or CCK-HIDA scan. Pancreatitis in children will usually have an underlying cause. Ultrasound and pancreatic enzyme levels will often confirm pancreatitis. Torsion of the spleen or the omentum is an uncommon cause of abdominal pain that can be diagnosed by ultrasound. Torsion of an epiploic appendage (the fat hanging off the colon) is only diagnosed at laparotomy or laparoscopy.

Although the GI mucosa does not have touch sensation, the bowel is acutely sensitive to distension, which is why constipation can cause abdominal pain. When cystic fibrosis is responsible for abdominal pain, even in older children, it is usually because of the distal intestinal obstruction syndrome (DIOS; formerly called meconium ileus equivalent).

In immunocompromised patients, right lower quadrant pain and tenderness usually indicates typhlitis (neutropenic enterocolitis) and not appendicitis. The inflammatory mass can be seen on CT scan and can be monitored with ultrasound. Treatment is generally nonoperative with broad-spectrum antibiotics. Recently, several studies of nonoperative (antibiotic only) management have been published. Even in selected patients, this appears to be only 70% effective, and long-term follow-up is not available.

Most medical diagnoses of abdominal pain can be ruled out by their lack of tenderness or guarding on physical examination. Patients with sickle cell anemia often have abdominal pain. They also usually have WBC counts of approximately 14,000 to 16,000/mm<sup>3</sup>, so this test is not helpful. If the physician is not sure of

the diagnosis even after CT scan, then treatment for sickle cell crisis, even including transfusion, is best. If the pain resolves, then the diagnosis was not appendicitis. If the pain does not resolve, then the patient needs to go to the operating room.

## ROLE OF THE PRIMARY CARE PHYSICIAN

The primary care physician must be able to recognize which patients with abdominal pain have an acute surgical abdomen. In brief, indicators of a possible acute surgical abdomen include the following:

- Pain lasting more than 1 hour that is severe enough to require analgesics
  - Bilious emesis
  - Acute abdominal pain lasting more than 6 hours
  - Obstipation
  - Localized abdominal tenderness
  - Guarding
  - Rebound
  - Guaiac-positive stools, melena, or hematochezia
- Indicators of nonsurgical problems include the following:
- Diarrhea
  - Symptoms of systemic illness: headache, sore throat, and myalgia
  - Emesis preceding pain
  - High fever very early in the illness
  - No abdominal tenderness

Ordering a complete blood count with differential and urinalysis is reasonable for the primary care physician when abdominal pain is the chief complaint. Examination by a pediatric surgeon before any other tests, including imaging studies, are ordered is in the patient's best interest. Certainly, when appendicitis is suspected, the diagnosis can often be made without resorting to imaging studies. When malrotation is in question, an upper GI series is the best test. However, if the patient already has signs of peritonitis and abnormal signs on plain-film radiograph, then prompt operation might be a better course. When intussusception is being considered, a diagnostic ultrasound or contrast enema is indicated unless signs of obstruction, peritonitis, or necrotic bowel are present, which should prompt immediate operation. When appendicitis is a possibility, the first imaging studies should be radiographs of the chest and abdomen. If the diagnosis is not clear, then an ultrasound followed by CT if necessary is the next step. The subtleties of the individual case might alter these judgments; involving the surgeon early will allow a more prompt and accurate diagnosis.

All patients with an acute surgical abdomen have volume depletion. Administering intravenous hydration at 150% of the maintenance requirement with appropriate solutions is reasonable unless there are signs of dehydration requiring more aggressive rehydration. Broad-spectrum antibiotics (ampicillin, gentamicin, and metronidazole) and analgesics (morphine) are also of benefit, but should probably be started only after consultation with the surgeon. If a patient is vomiting or has marked abdominal distension, then a nasogastric tube should be placed.

Certainly, any patient with abdominal pain as any part of their chief complaint should not have any food or drink until a diagnosis and disposition are decided.

## IMPROVING DIAGNOSTIC ABILITY

Making a diagnosis is certainly the most difficult task in medicine. Knowledge of the prevalence of a disease can aid the differential diagnosis (Table 347-1 and Table 347-2).

This information allows emergency department personnel or the primary care physician to evaluate the child with abdominal pain in an efficient and accurate manner. The physician should consider common conditions first while evaluating a child with abdominal pain. Once these possibilities are exhausted, which will be rarely, the physician can look for more esoteric diseases.

## TOOLS FOR PRACTICE

### Medical Decision Support

## Chapter 348 AIRWAY OBSTRUCTION

Carol Conrad, MD; David N. Cornfield, MD

Respiratory distress is common in children. An airway obstruction can be precipitated acutely by infections, trauma, inhalational injury, a mass lesion, or foreign-body aspiration. In addition, an acute illness can significantly worsen an obstruction caused by either a chronic process or an anatomic abnormality. An acute upper airway obstruction presents an immediate threat to life. If the airway obstruction is relieved quickly, then rapid clinical improvement can occur. An

acute airway obstruction can occur throughout the respiratory tract. A knowledge of developmental respiratory physiology and anatomy, combined with historical information, can help determine the anatomic site of the obstruction. Definitive treatment and relief of the obstruction is critical to prevent hypoxic-ischemic injury.

An airway obstruction and the adverse effects of hypoventilation result either from blockage of the airway from aspiration of a foreign object, from mucus plugging, when the inner diameter of the airway is reduced (as occurs with mucosal edema in the case of acute laryngotracheobronchitis), or with constriction of the peribronchiolar muscles (as occurs with status asthmaticus).

Alternatively, the airway can be compressed from an external mass, such as a mediastinal tumor. The onset can seem to occur quite rapidly, even with a slowly growing tumor. A patient with a chronic airway obstruction, such as a prematurely born infant, can experience an acute airway obstruction caused by an acute viral infection, such as respiratory syncytial virus bronchiolitis.

Infants have a greater incidence of respiratory compromise than older children because they have a smaller airway diameter and exponentially increased airway resistance. In addition, the connective tissue in infants has incompletely hardened cartilaginous structures (malacia). This is the case for the cartilaginous structures such as the larynx (epiglottis, aryepiglottic folds, arytenoid cartilage, tracheal cartilage), the trachea, bronchi, bronchioles, and the chest wall itself. As a result, any increase in airway obstruction results in relatively higher airflows, thereby increasing the dynamic obstruction caused by relatively flexible airway structures. In infants younger than 1 year, collateral lower airway circulation in the alveoli and the bronchioles, the pores of Kohn, and the canals of Lambert are absent, predisposing the infant to atelectasis. The narrowest portion of the airway in the infant and child is the cricoid ring, unless an infant is born with congenital airway anomalies such as tracheal stenosis or bronchomalacia. In the older child and adolescent, the narrowest portion of the airway is the vocal cord aperture.

## INITIAL ASSESSMENT

To determine whether a child requires emergent intervention, consideration should focus on upper airway patency, the degree of respiratory effort, and the effectiveness of respiratory function. A complete upper airway obstruction or respiratory failure demands immediate intervention. The child should be kept calm and comfortable. Anxiety and crying can substantially increase dynamic airway obstruction and the work of breathing in young children. Simple observation of the child, without a detailed examination, is an invaluable tool. By determining the respiratory rate, whether the child is using accessory muscles, has retractions, recognizes parents, can speak, or can suck on a bottle or pacifier, the physician can match the appropriate level of support to the condition of the child.

## HISTORY

Contingent on the degree of acuity, historical information can be obtained before initiating therapy. Historical information can establish a cause for the respiratory disease. An acute onset, particularly in the absence of fever, prompts concern about an aspirated foreign body. Conversely, if a child has had respiratory problems before the acute process, then a dynamic obstruction caused by underlying laryngomalacia, subglottic stenosis, or malacia of the trachea or bronchus may be worsened by superimposed infection or reactive airway disease.

The pulmonary history should elicit information regarding the duration of the problem and factors that either worsen or improve the signs or symptoms. Historical information regarding the prenatal and neonatal periods can guide diagnosis and treatment. A history of decreased fetal motion may indicate a neuromuscular disorder that can lead to alveolar hypoventilation and restrictive chest wall disease. A history of oligohydramnios can indicate the presence of pulmonary hypoplasia. A knowledge of whether resuscitation efforts were required in the perinatal period and for what reason is helpful. The gestational age at birth and whether the infant required intubation, mechanical ventilation, or supplemental oxygen can provide information regarding the presence of either upper or lower respiratory tract disease. The quality of a child's cry can provide information regarding vocal cord function and tracheal patency. A history of cyanosis in the absence of cardiac anomalies may prompt concern over respiratory disease. A prior history of wheezing or cough responsive to bronchodilator therapy could indicate asthma. Often, children with recurrent episodes of cough have associated gastroesophageal reflux disease (GERD). Immune compromise may be suspected in children with prior episodes of pneumonia.

## PHYSICAL EXAMINATION

The initial evaluation should include careful observation. Observation of the child and of the quality and timing of the respiratory pattern is important. Close attention to the child's work of breathing, level of consciousness, and degree of interaction can be particularly instructive. Attention to whether accessory muscles are being used, the relative ratio of inspiration to expiration, and movement of the head and neck with respirations provide important clinical information. By approaching the child from a distance and observing the child in the relative comfort of parental arms, an assessment can be made without biasing the examination by introducing fear and anxiety. Careful attention to the facial expressions of the child can provide further insight into the clinical presentation. The child with incipient respiratory collapse may demonstrate furrowed eyebrows, may be unable to regard and to focus on the examiner, and may seem fatigued and anxious. The child may demonstrate nasal flaring and may be pale and diaphoretic. Cyanosis may be present, but this is a late finding in children who do not have a previous history of cyanotic heart disease.

**Table 348-1** Sounds Produced From the Lower Airway

SOUND (ATS)	FREQUENTLY USED SYNONYM	ACOUSTIC CHARACTERISTICS	LIKELY LOCATION OF FLUID, MUCUS, OR OBSTRUCTION
<b>Crackle</b>	—	Usually inspiratory sound	—
Coarse	Rhonchi	Loud, low in pitch	Large- or medium-sized bronchi
Fine	Rale	Softer and shorter in duration, higher in pitch	Alveoli or small bronchioles
<b>Wheeze</b>	—	Usually expiratory sound	—
High pitched		Long, musical	Small airways, typical of asthma
Low pitched		Loud, long, sonorous	Large airways, such as bronchi or trachea, such as in tracheo- or bronchomalacia

ATS, American Thoracic Society.

From Pasterkamp H, Kraman S, Wodicka G, et al. Respiratory sounds: advances beyond the stethoscope. A state of the art review. *Am J Respir Crit Care Med*. 1997;156:974–987. Reprinted by permission of the American Thoracic Society.

Abnormal breath sounds and physical examination findings are either more prominent on the inspiratory or the expiratory phase of breathing depending on the site of disease. In the presence of complete upper airway obstruction, no effective air movement is present. In such an emergency situation, the child would be unable to cough audibly, speak, or produce any sound. Audible phonation or breath sounds indicate airway patency, though partial obstruction may be present. Partial extrathoracic upper airway obstruction results in stridulous respirations with increased obstruction to airflow on inspiration relative to expiration. Retractions and nasal flaring with diminished air movement or worsening hypoxemia (poor color and decreased mental status) portend impending respiratory failure.

Children with respiratory failure have inadequate oxygenation, ventilation, or both. Children in extremis look ashen, obtunded, lethargic, or extremely anxious. Central cyanosis may be present. Chest wall movement may be diminished because of weak or inefficient breaths, thereby decreasing any signs of respiratory distress. Extreme tachypnea can precede hypopnea. Given that respiratory insufficiency leads to respiratory failure, as children develop overt failure, the pattern of respirations becomes irregular. In the presence of a tenuous airway, avoiding components of the examination that will increase the child's anxiety is prudent. Comprehensive airway evaluation ought to be deferred pending the presence of critical care personnel and access to equipment that will allow for definitive airway management if necessary.

For the chest examination, the physician should observe the breathing pattern and respiratory effort. Removing the child's shirt allows observation of the accessory muscles of respiration and how they are used. Children with obstructive disease (cystic fibrosis and asthma) may have a prolonged expiratory phase and a hyperinflated thorax that may be clinically evident as an increase in anteroposterior diameter. A normal inspiratory/expiratory ratio is 1:2. In the presence of small airway obstruction, the ratio is 1:3 or 1:4. Children with restrictive lung disease breathe rapidly and with smaller tidal volumes. The physician should

inspect the chest wall for symmetry, pectus deformity, and the size of the thorax. Retractions are more clinically apparent in younger children than in adolescents and adults, owing to the relatively high compliance of the chest wall. Retractions are evident in the lower part of the thorax as the rib cage is pulled inward with diaphragmatic contraction on inspiration. Head bobbing results from the use of the suprasternal accessory muscles of respiration and is a sign of increased airway resistance. The degree of respiratory effort required is directly proportional to the degree of obstruction. Percussion of the thorax can reveal localized air trapping, hyperresonance, or lobar consolidation or dullness.

When auscultating breath sounds, the physician should listen for crackles, wheezing, or stridor. The physician should also determine whether the sounds occur on inspiration, on expiration, or throughout the respiratory cycle. The distribution, pitch, and quality of sounds can differentiate between upper and lower airway pathology. Table 348-1 describes the types of sounds that can be appreciated in various forms of disease as described by the American Thoracic Society and the American College of Chest Physicians. Causes of intra- and extrathoracic obstructing lesions of the upper airway are detailed in Table 348-2. A lesion in the extrathoracic trachea increases airflow resistance primarily during inspiration and is characterized by stridor. Obstruction in the intrathoracic trachea results in an increase in airflow resistance during expiration and is clinically characterized by wheezing. A lesion may be *fixed* or *variable*. If airflow limitation does not vary during the respiratory cycle, then the lesion is fixed. Noise that occurs on both inspiration and expiration suggests a fixed stenosis of the airway.

In a child or infant, the dynamics of the lesion can be assessed for the change in character of the stridor by making the child breathe more forcefully. By making the child inspire with high inspiratory flow, a dynamic compression (an acute airway narrowing) will develop below an extrathoracic lesion and above an intrathoracic lesion. Variable lesions are those that can be distended or compressed during the phases of

**Table 348-2** Localize the Source of the Noise

LESION	NOISE	
	INTRATHORACIC LOCATION	EXTRATHORACIC LOCATION
<b>Fixed</b> Tracheal stenosis Double aortic arch anomaly Cricoid ring	Noise occurs on inspiration and expiration	Noise occurs on inspiration and expiration
<b>Variable</b> Foreign body aspiration Laryngomalacia	Wheeze predominates on expiration	Stridor dominates on inspiration

CT, computed tomography.

respiration. An extrathoracic variable obstruction (laryngomalacia) worsens on inspiration and improves during expiration, given that positive intraluminal pressures will distend this portion of the airway during exhalation but will compress the airway during a forceful inhalation. A variable intrathoracic obstruction is primarily appreciated on expiration, given that the airway is dilated on inspiration by the negative intrathoracic pressure but compressed during forceful exhalation.

## DIFFERENTIAL DIAGNOSIS

The causes of airways obstruction differ at various developmental stages. A summary of the causes of stridor in children is found in Table 348-3. Determining the correct pathological cause of the obstruction entails consideration of the child's age.

## NEONATES

### Laryngomalacia

Infants have more compliant chest walls and soft tissue, breathe faster, and have smaller-caliber airways than older children. These factors combine to increase the likelihood that infants will have respiratory difficulty. The most common cause of stridor in an infant is laryngomalacia. The onset is typically within the first 2 weeks of life. The stridor is positional, with greater severity when the infant is lying supine and diminished severity with prone positioning. Stimuli that increase the rate of airflow on inspiration, such as crying, feeding, or an upper respiratory tract infection, worsen the dynamic inspiratory obstruction associated with laryngomalacia. The symptoms come from immature cartilaginous structures of the larynx. The condition can aggravate underlying gastroesophageal reflux.

Moreover, the relatively more negative intrathoracic pressure that is necessary to bypass the dynamic and intermittently obstructive upper airway can result in microaspiration. Generally, laryngomalacia worsens in the first several months of life and resolves by the end of the first year.

In severe cases of laryngomalacia with constitutional symptoms of failure to thrive or an evolving chest wall deformity, epiglottoplasty with or without tracheostomy may be necessary. Respiratory distress, thoracic deformities (caused by severe and chronic retractions), failure to thrive, and hypoxia may occur in severe cases. Generally, diagnosis can be achieved with a complete history and physical examination. Definitive diagnosis, often unnecessary, can be made with flexible laryngoscopy. Endoscopically, the epiglottis folds over the larynx on inspiration as the arytenoid cartilages move to the midline on inspiration. Infants with laryngomalacia often have feeding problems and may exhibit coughing or choking when they feed as their first symptom. Stridor often worsens with minor respiratory tract infections. Through continuous noninvasive monitoring, studies have demonstrated that infants who have laryngomalacia are more likely than age-matched controls to have transient, albeit nonlife-threatening, episodes of hypoxemia and hypercapnia. As their disorder improves over time, these infants rarely require an artificial airway.

### Vocal Cord Paralysis

Unilateral or bilateral vocal cord paralysis may occur in otherwise healthy newborns and has been associated with birth trauma. A neonate with a shoulder dystocia, forceps delivery, or vacuum extraction is more likely to have unilateral vocal cord paralysis than a neonate experiencing an atraumatic delivery. Trauma associated with airway instrumentation can cause vocal cord paralysis as well. Infants intubated in the delivery room or those who have undergone mechanical ventilation may also have injury to the vocal cords as a result of airway instrumentation. The diagnosis is best made by flexible laryngoscopy while the baby is breathing spontaneously. If the endoscopic evaluation is performed during positive pressure ventilation, discerning vocal cord paralysis is difficult. However, performing the examination through a laryngeal mask allows for positive pressure ventilation noninvasively and can provide excellent visualization of the vocal cords. In the spontaneously breathing child with vocal cord paralysis, the true cord or cords move passively to the midline with inspiration. Unilateral cord paralysis caused by stretching of the recurrent laryngeal nerve often requires no specific therapy and resolves over time. However, surgical transection of the recurrent laryngeal nerve that might occur during surgical correction of congenital heart anomalies will result in permanent paralysis. Bilateral cord paralysis is associated with chronic aspiration and hypoxemia. In the presence of bilateral paralysis, a tracheotomy may be necessary.

To determine the feasibility of feeding the infant, a video swallowing study is essential. In some cases, infants can protect the airway by consuming highly

textured, thickened food, but they are unable to do so if thin food is consumed.

Vocal cord paralysis may also result from elevated intracranial pressure, a congenital Arnold-Chiari malformation, or from an intracranial mass as a result of nerve compression. In the presence of bilateral cord paralysis, determining the underlying cause is particularly important. In an otherwise healthy child whose vocal cord paralysis is thought to be caused by birth trauma, improvement over time is the rule.

Data indicate that vocal cord paralysis, either unilateral or bilateral, is a relatively common complication of congenital heart disease surgery. In the presence of a patent ductus arteriosus, the recurrent laryngeal nerve can be compressed, resulting in unilateral vocal cord paralysis. In the course of repairing congenital heart disease, injury to the recurrent laryngeal nerve often occurs, leading to vocal cord paralysis. Continuation on the lesion, the incidence may be approximately 10%.

### Extrinsic Compression of the Trachea

Compression of the trachea can lead to stridor. Potential causes of airway compression include thyroglossal duct cyst, ectopic thyroid tissue, esophageal duplication cyst, lymphoma, cardiac anomaly, or vascular anomaly. The optimal diagnostic and therapeutic approach depends on the condition of the child and the rate of progression of the symptoms. Clearly, a relatively asymptomatic patient with gradual onset can be evaluated at a less urgent pace than an acutely ill child with rapidly progressive illness.

### Craniofacial Anomalies

Congenital craniofacial anomalies can place newborns and older children at risk for chronic and severe obstructions of the upper airway. An obstruction of the upper airway can occur because of micrognathia (Pierre Robin sequence and Treacher Collins syndrome), macroglossia (Beckwith-Wiedemann syndrome), small mid-face or small oropharyngeal space (achondroplasia), and adenotonsillar hypertrophy (Down syndrome). Macroglossia can develop in children with lipid or glycogen storage disorders; this anomaly is rarely present at birth and develops slowly. Apnea studies that monitor nasal and oral airflow, chest wall movement, and pulse oximetry or a full polysomnogram can grade the level of severity of hypoventilation and hypoxemia in these children. Some infants require treatment with noninvasive or invasive (via tracheostomy) mechanical ventilation before reconstructive surgery can be performed.

### Tracheomalacia

Tracheomalacia is a congenital disorder of the trachea characterized by respiratory distress and wheezing. Typically, symptoms appear before the infant is 2 months old. The predisposing risk factors include a previous history of intubation, prematurity, and gastroesophageal reflux. Tracheomalacia results from incompletely formed cartilaginous rings. Normally, the cartilaginous component of the trachea comprises approximately two-thirds of the airway

circumference, with the membranous trachea comprising the remainder of the tracheal circumference. In tracheomalacia, the proportion of membranous to cartilaginous trachea is increased, resulting in poorly supported tracheal structures. Depending on the position of the diminished cartilaginous structure in the airway, the dynamic obstruction to airflow may be more apparent in inspiration or expiration. If the tracheomalacia is particularly severe, both phases of respiration may be affected. Tracheomalacia can be either primary or secondary. The primary form is characterized by relatively decreased cartilage in the tracheal rings. Secondary tracheomalacia results from extrinsic compression of the trachea. Causes of extrinsic compression might include an anomalous vascular structure, mediastinal tumor, lymphadenopathy, or enlargement of the left atrium.

The child with moderate or severe tracheomalacia exhibits chronic wheezing that is often diagnosed as asthma. Many premature infants have some component of tracheo- or bronchomalacia. In children with tracheomalacia, treatment with  $\beta$ -agonists may relax the tracheal smooth muscle in the membranous trachea and increase the flaccidity of the tracheal tone, thereby worsening airflow obstruction. The use of medications that increase tracheal airway smooth-muscle cell tone (eg, ipratropium bromide, bethanechol) can improve airflow.

## CHILDREN BEYOND THE NEONATAL PERIOD

### Acquired Infectious Causes of Airways Obstruction

Croup (laryngotracheobronchitis) is the most common cause of upper respiratory obstruction in childhood, with peak incidence in the second year of life (range: 6 months to 3 years). (See Chapter 352, Croup [Acute Laryngotracheobronchitis]), for more information.) Admission rates for croup in children seen in outpatient settings range from 1.5% to 31% of cases seen; these figures vary widely, depending on hospital admission practices and the severity of the disease in the population being assessed. Croup occurs most commonly in late fall and early winter. Croup is caused by inflammation and edema of the mucosal and submucosal tissues of the subglottic space. The swollen mucosa expands into the airway lumen and narrows the trachea.

Most children with croup have an uncomplicated course and are managed without formal medical care. Only a small percentage of children who require urgent care require hospitalization. Croup is diagnosed clinically and causes a barking cough, hoarse voice, high-pitched inspiratory stridor, and fever. The clinical presentation follows a prodrome of mild fever and upper respiratory tract infection symptoms lasting several days. Croup severity is generally worse at night compared to daytime. Mild croup is characterized by an intermittent barking cough, stridor only with agitation, mild tachypnea, and tachycardia. A child with mild croup is minimally distressed, well hydrated, and has a normal mental status. Moderate croup produces audible stridor at rest, worsening stridor with

agitation, a barking cough, and increased work of breathing (retractions, tachypnea, tachycardia). A child with moderate croup may be fussy but is alert, interactive, and comforted by parents. Hypoxia is atypical in mild or moderate croup. Laboratory tests are nondiagnostic. Radiographic studies of the neck are confirmatory but do not alter management and are not necessary in most cases. Classically, the trachea looks narrowed in the subglottic space in a characteristic steeple-like appearance on anteroposterior chest/airway radiographs.

### Peritonsillar Abscess and Retropharyngeal Abscess

Peritonsillar and retropharyngeal abscesses are common infections that occur in childhood and can be life threatening. A retropharyngeal abscess occurs most commonly in children between the ages of 2 and 4 years. A retropharyngeal abscess may extrinsically compress structures in the upper airway. Prominent presenting complaints are usually neck pain, fever, and sore throat rather than acute, severe airway obstruction. The symptoms caused by a retropharyngeal abscess relate to the pressure and inflammation produced by the abscess on either the airway or the upper digestive tract and pharynx. The patient may have intense dysphagia, drooling, and odynophagia, or some element of respiratory distress from edema and inflammation of the airway (stridor, tachypnea, or both) may be present. An unwillingness to move the neck because of discomfort is often a prominent presenting feature and should lead to consideration of retropharyngeal abscess if the child is febrile and irritable. Usually, extension of the neck is affected more than flexion. This circumstance causes the patient to hold the neck stiffly or have torticollis.

A peritonsillar abscess is the most common deep-neck infection in children and adolescents, accounting for at least 50% of cases. A peritonsillar abscess generally occurs in later childhood and adolescence, although it can occur at any age. (See Chapter 311, Pharyngitis and Tonsillitis.) The sudden onset of severe respiratory distress is rare. The infection is usually in the superior pole of the tonsil, where a defined collection of pus is located between the tonsillar capsule, the superior constrictor, and the palatopharyngeus muscle. The typical clinical presentation of peritonsillar abscess is a severe sore throat, fever, and a *hot-potato* muffled voice. Drooling may be present. Trismus is common; patients will often have swelling of the neck and complain of neck pain. The discomfort associated with the peritonsillar abscess creates fatigue and irritability in the patient.

### Bacterial Tracheitis

Bacterial tracheitis has been termed membranous croup, bacterial croup, and pseudomembranous croup. Although the incidence is low, bacterial tracheitis is a serious illness. It generally affects children between 4 and 8 years of age. The pathogenesis of bacterial tracheitis remains controversial. Bacterial tracheitis often occurs as a secondary bacterial infection complicating a preexisting viral infection, including adenovirus, influenza A, and influenza B. Bacteria

gain access to the trachea epithelium after a viral infection that compromises epithelial integrity. A tracheal epithelial inflammation occurs, and thick mucopurulent secretions accrue. Although *Staphylococcus aureus* formerly was the primary causative organism, more recently the predominant organisms are *Moraxella catarrhalis*, Streptococcal species, and oral anaerobes. The incidence of bacterial tracheitis caused by *Haemophilus influenzae* is decreasing because of the routine practice of *Haemophilus influenzae* b (Hib) childhood vaccinations in most areas of the United States.

Bacterial tracheitis can be distinguished from croup by the child's age and the degree of toxicity (Table 348-4). Children commonly experience a viral prodrome of fever, barking cough, and stridor. In contrast to croup, in bacterial tracheitis, symptoms worsen over time. To evaluate the child, lateral and anteroposterior radiographs of the neck and chest may be helpful. Findings on plain-film radiographs include subglottic narrowing, a ragged edge to the usually smooth tracheal air column, and a hazy density within the tracheal lumen. The epiglottis and supraglottic structures seem normal on neck films. In the event of respiratory collapse or an inability to mobilize secretions effectively, mechanical ventilation is necessary. Careful attention to the suctioning and mobilization of secretions is essential. Occlusion of the endotracheal tube has been reported as a common cause of death in intubated and mechanically ventilated children with bacterial tracheitis. For this reason, some otolaryngologists have advocated for expectant placement of tracheotomy tubes in children with bacterial tracheitis, because tracheostomy canulas can be rapidly and safely replaced in the event of

obstruction with tenacious secretions. Antibiotics and supportive care are essential for full recovery. Complications associated with bacterial tracheitis include toxic shock syndrome, septic shock, postintubation pulmonary edema, acute respiratory distress syndrome, and subglottic stenosis.

### Epiglottitis

Acute epiglottitis is a potentially life-threatening infection of the supraglottic structures, and can lead to a sudden, fatal airway obstruction if treatment is delayed. Classically, the disease does not involve the subglottic or tracheal mucosa. If treatment is delayed in young children, the condition may rapidly progress to a complete airway obstruction with cardiorespiratory arrest.

Acute epiglottitis was initially described as a disease of adults, but events occurred that led to an epidemiologic shift in the 1960s and it became primarily a pediatric disease, with an incidence of 1 per 100,000 children by 1993. Before the introduction of the Hib vaccine, invasive disease from *H influenzae* occurred at a rate of 116 per 100,000 children in 1986, and this was the organism most often cultured in children with epiglottitis. After the introduction of the conjugate vaccine against *H influenzae* type b in 1985, the incidence of invasive disease from *H influenzae* decreased dramatically, and was accompanied by a dramatic decline in the incidence of acute epiglottitis in children.

As the frequency of Hib disease decreased, the infectious etiology of epiglottitis shifted toward other causative organisms. In this era, in which vaccination for many Streptococcal serotypes has been introduced into the routine vaccination schedules

**Table 348-4**

**Comparison of Epiglottitis, Laryngotracheobronchitis, Spasmodic Croup, and Bacterial Tracheitis**

FACTOR	EPIGLOTTITIS	VIRAL CROUP	SPASMODIC CROUP	BACTERIAL TRACHEITIS
Age (yr)	2–6	0.6–2	0.5–3	4–8
Cause	<i>Haemophilus influenzae</i> type b	Parainfluenza 1,2,3	Gastroesophageal reflux, asthma	<i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> type b
Season	All year	Late spring, late fall	All year	All year
Clinical presentation	Child sitting Toxic Drooling Dysphagia Muffled voice	Child lying down Nontoxic Barking cough Hoarseness	Nontoxic Barking cough Hoarseness	Toxic Barking cough
Onset prodrome	Rapid, over a few hours	Variable; few hours to 4 days	Sudden	Variable; few hours to 5 days
Stridor	Less common	Common	Very common	Common
Fever	High	Low-grade	Afebrile	High
Chest retractions	Less common	Common	Common	Common
Lateral neck film	Swollen epiglottis	Subglottic narrowing	None	Pseudomembrane
Progression	Rapid	Usually slow	Rapid	Usually slow
Recurrence	Rare	Common	Very common	Rare

recommended by the Centers for Disease Control and Prevention and the American Academy of Pediatrics, most cases are thought to be caused by other bacteria, such as *S aureus*, *M catarrhalis*, *Pseudomonas* species, *Candida albicans*, *Klebsiella pneumonia*, *Pasturella multocida*, and *Neisseria* species. Bacterial superinfection of viral infections is also common, particularly with herpes simplex, parainfluenzae, varicella-zoster, and Epstein-Barr.

Epiglottitis occurs throughout the year, but mainly during the 6-month period from December to May. It previously occurred equally in males and females with a slight male predominance between the ages of 2 and 6 years of age, though more recently, the epidemiology shifted again toward significantly older patients.

The onset of epiglottitis is usually abrupt, preceded by a minor upper respiratory infection in some cases. The onset is characterized by high fever, toxic appearance, and sore throat that progresses over a few hours to dysphagia, drooling, and respiratory distress. The patient seems anxious and irritable. Stridor is a late finding. Breathing becomes noisy, and the voice and cry are muffled as swelling of the aryepiglottic folds and supralaryngeal mucosa swells and obstructs the glottic inlet. The patient tends to sit forward in the "sniffing position" with the neck hyperextended in order to increase airway patency. Complete airway obstruction may occur at any time without any preceding deterioration in clinical signs.

A very high index of suspicion must be maintained, and epiglottitis should be considered in every child with apparent acute upper airway obstruction who has a high fever and sore throat, and especially when those signs developed over a few hours. A lateral neck radiograph can be helpful, though should only be attempted if the patient is stable and the diagnosis is in doubt, since the condition can progress rapidly. Therapeutic trials of inhaled medicines such as corticosteroids or racemic epinephrine should not be initiated, as time is wasted, and the child may become more irritated upon manipulation, leading to complete obstruction of the airway. Additionally, direct visualization of the epiglottis should not be undertaken until the child is undergoing tracheal intubation.

Most fatalities occur within the first few hours after the patient has arrived at the hospital. All deaths result from complete airway obstruction. Once the diagnosis is made, there should be no delay in establishing an artificial airway. If there is time, the child should be intubated in the operating room under general anesthesia by personnel who can perform emergency tracheostomy if intubation fails. Corticosteroids and epinephrine have been used in the past. However, there is no good proof that these medications are helpful in cases of epiglottitis.

Between 10% and 25% of cases may be managed by observation; these are normally older children with larger airways, although mortality is higher in this group historically. The normal treatment algorithm is as follows:

1. Avoid disturbance until an airway is secured. Allow the child to sit up and stay in his parent's arms so as to avoid agitation.
2. Give 100% oxygen by blow-by administration.

3. Perform a radiologic study of the lateral neck, only if the child seems stable and has no stridor.

4. Intubate in the operating room.

5. Sedate (after intubating).

6. Intravenous antibiotics may effectively control inflammation and rid infection from the body.

A pediatric ear, nose, and throat surgeon should be contacted immediately, and should be the only physician to try to visualize the airway. The medical and surgical team should be ready to emergently place an endotracheal tube, and also be ready for emergent tracheotomy. It is best for the surgeons to visualize the airway when in the operating room. All children who are suspected of having bacterial epiglottitis should be admitted to the hospital for IV antibiotic treatment and intensive care monitoring. Antibiotics are prescribed to treat the most common types of bacteria. Blood cultures are usually obtained for the potential verification of an organism. Generally, amoxicillin/clavulanic acid or ceftriaxone are extremely effective.

### Laryngeal Papillomatosis

Respiratory papillomatosis is a disease caused by infection of the airway by human papilloma virus (HPV). The lesion is benign but can transform to a malignant lesion, particularly in the lung parenchyma. More commonly, HPV is life threatening if the aggressive growth and rapid proliferation of the papilloma lesions in the airway cause airway obstruction. HPV infection in children is most commonly acquired as the neonate passes through the birth canal. HPV-6 and -11 are the most common subtypes in this population, as is true for genital HPV infection in women.

In most instances, children with HPV infection of the larynx exhibit hoarseness, though advanced cases can have stridor and respiratory distress. Most commonly, it occurs on the vocal cords but can infect the trachea and even the bronchi. In children, HPV infection of the larynx is usually diagnosed at age 2 to 4 years. The growth of the papilloma will be more aggressive the earlier it occurs. Treatment is generally focused on removing the obstructing lesions with laser ablation of the root of the papilloma to prevent regrowth. Often, repeated ablations are necessary as lesions regrow at sites of ablation. Vaccine trials and adjuvant therapies using antivirals such as  $\alpha$ -interferon injected into the lesion are being evaluated as therapeutic alternatives. A case report published in 2011 discusses the sustained remission in a 5-year old child with recurrent HPV infection of the larynx after treatment with the quadrivalent HPV vaccine. Clinical trials with bivalent and quadrivalent vaccines have demonstrated greater than 95% efficacy in preventing infection in HPV-naïve recipients. Data regarding transvaginal infection rates are not yet published. When there is a clinical need to instrument the airway, great care must be taken to avoid introducing infection by inoculating the more distal components of the airway with viral particles.

### VASCULAR ANOMALIES

Stridor or dysphagia can be a manifestation of extrinsic compression of the airway or esophagus by an anomalous vascular structure. The anomalies result

from abnormal persistence or regression of embryonic structures. The most common anomaly—aberrant right subclavian artery—produces minimal symptoms. In many cases the only clinical manifestation is dysphagia caused by compression on the esophagus. A barium swallow can yield diagnostic information. In the presence of a severe obstruction, infants can be quite ill. Poor feeding may lead to failure to thrive. Wheezing and stridor may be consistently present and exacerbated by feeding. In the most profound cases, cyanosis and apnea may occur.

In the presence of a right-sided aortic arch, a child may experience vascular impingement on the airway as a result of a double aortic arch, wherein the aortic arches encircle the esophagus and trachea. The disease results when resorption of the fourth embryonic aortic arch is incomplete. The problem may cause stridor or wheezing. The right and left arches compress the right and left sides of the trachea and the esophagus. The right arch indents the esophagus posteriorly. Division of one of the arches, usually the smaller posterior, opens the constricting ring and is curative.

In the context of right-sided arches, a residual patent ductus arteriosus or ligamentum arteriosum can form a complete ring around the airway. A division of the ductus or ligamentum is curative. Occasionally, a carotid or innominate artery compresses the anterior margin of the trachea. This compression may show on radiographs of the tracheal air column or on a tracheogram, but the esophagram is normal. If needed, the compressing artery can be displaced anteriorly at surgery.

Although not a vascular ring, the anomalous left pulmonary artery also causes an airway obstruction. The left pulmonary artery arises from the right pulmonary artery and passes between the esophagus and trachea, compressing the trachea and the right main bronchus. This lesion causes compression on the anterior edge of the esophagus. A collapse or hyperinflation of part of the right lung may occur. Diagnosis is made by a combination of esophagrams, bronchoscopy, computed tomographic angiography, or magnetic resonance imaging. The surgical reattachment of the left pulmonary artery to the main pulmonary artery relieves the obstruction, but residual tracheomalacia may be present.

## ACQUIRED, NONINFECTIOUS CAUSES OF AIRWAYS OBSTRUCTION

### Vocal Cord Dysfunction

Vocal cord dysfunction (VCD) is characterized by the inappropriate adduction of the vocal cords during inspiration. Typically, vocal cord dysfunction causes a sudden onset of labored breathing with inspiratory stridor. The sound is often erroneously characterized as wheezing. For some patients, the symptoms are precipitated by physical activity. The inappropriate adduction during inspiration may result in severe airflow limitation characterized by profound, high-pitched stridor and dyspnea. The acute onset and severity of symptoms in some children with VCD have resulted in intervention with endotracheal intubation

or tracheotomy for severe upper airway obstruction. Diagnosis entails flexible laryngoscopy during an acute exacerbation. Subsequent to the definitive diagnosis, patient education, speech therapy, and biofeedback have produced favorable results. Techniques taught by a speech therapist who is familiar with this disorder result in the ability of patients to control vocal cord movement in the event that symptoms recur. Techniques focus on training the extrinsic laryngeal muscles. In the short term, this treatment course is associated with high rates of success.

The diagnosis of VCD is often complicated by an initial diagnosis of asthma. Current data indicate that VCD is often a self-limiting disorder. Most patients have no long-term sequelae once the diagnosis has been established. For some patients, only high-level exercise can precipitate the VCD. For such patients, insight-driven biofeedback is difficult to use. Data suggest that the use of ipratropium bromide may be a safe and effective measure for treating exercise-induced VCD.

### Anaphylaxis

Anaphylaxis and anaphylactoid reactions may be severe and life threatening when edema involves the retropharynx or larynx. The increasing incidence of food allergies correlates with more anaphylactic reactions. The onset of symptoms is usually sudden. Presenting signs and symptoms can include urticaria and facial edema. Treatment must be initiated immediately. Initial therapy should include the intramuscular injection of epinephrine. Patients at risk for an anaphylactic reaction should always have immediate access to portable epinephrine devices that can be used in an ambulatory setting (home or school) when the first signs of anaphylaxis are noted. Even if the device is effective, the patient should be transported to a local emergency room for monitoring as the effects of initial treatment wane and to ensure that the late phase of the allergic response does not compromise the child. After the initial treatment with epinephrine, systemic corticosteroids should be provided to mitigate any biphasic or prolonged effect of the allergic response.

### Foreign-Body Aspiration

Foreign-body aspiration (FBA) is a common and potentially life-threatening event. The number of emergency room visits for FBA in 2001 exceeded 17,000. Less than 1% of these events resulted in death, though the estimated number of deaths per year caused by foreign body aspiration ranged between 22 deaths per year average between 1972 and 1992 to 160 deaths in 2000 in the United States. Most of these events occur in children younger than 3 years, and the peak incidence occurs between 1 and 2 years of age. The most commonly aspirated objects are peanuts and other types of nuts and seeds, food particles, hardware, and pieces of toys. Balloons are the most common object involved in fatal FBA, but aspiration of small marbles and balls results in considerable morbidity and mortality. Foreign bodies that lodge in the back of the mouth/throat and above the vocal cord can cause complete obstruction and death. Most foreign bodies that are aspirated are found in the major bronchi and

do not entirely block the airway; laryngeal and tracheal foreign bodies are less common. The right lung was involved in 60% of cases, the left lung in 23% of cases, the trachea or carina in 13%, and the larynx in 3%. Bilateral FBA occurred in 2% of cases.

The presentation of FBA depends on whether the event was witnessed, the age of the child, the type of object aspirated, the amount of time that has elapsed since the event, and the anatomic location of the object. A presentation and diagnosis within 24 hours of aspiration occurs in approximately 50% to 75% of cases. Children who have signs of severe respiratory distress, such as cyanosis, stridor, or wheeze, and altered mental status have to be evaluated and treated immediately with a rigid bronchoscopic removal of the foreign body. More commonly, the situation is less emergent. The examination may reveal localized wheezing, cough, and diminished breath sounds, but these are not universally present. A history of choking or a sudden onset of coughing, dyspnea, or cyanosis may be present in a previously healthy child. The choking phase occurs immediately after the episode but tends to resolve quickly because of tachyphylaxis of cough receptors in the lower airways. The lack of ongoing symptoms should not be construed as a sign of resolution, given that a delay in diagnosis may result in chronic infection of the lung parenchyma distal to the foreign body. Children may have fever and other signs of pneumonia.

Plain-film radiographs may or may not be helpful in establishing the diagnosis of FBA. If the child is able to cooperate, then chest radiographs obtained in the exhalation phase can demonstrate asymmetric gas trapping. Given that most inhaled objects are not radiopaque, direct radiographic evidence of their presence is absent. Other radiographic signs can include focal segmental or entire lung hyperinflation, atelectasis, mediastinal shift, and pneumonia. Hyperexpansion of the lung distal to an obstruction is exaggerated on expiratory views because of ball-valve obstruction. In young children for whom expiratory views may be difficult to obtain, a substitute can be obtained using 2 lateral decubitus views. The lower side is the “expiratory” view.

The most sensitive and specific method is that of direct visualization by bronchoscopy. If the index of suspicion is high, then an otorhinolaryngologist or general surgeon should be consulted. In children, a rigid bronchoscopy is the preferred mode of visualization and airway instrumentation, because the rigid bronchoscopy provides control of the airway throughout the removal process. If the index of suspicion is lower, flexible bronchoscopy by the pulmonologist is merited for diagnostic purposes. Lodged nasal foreign bodies should be removed quickly, particularly corrosive objects such as nickel batteries. (See Chapter 251, Foreign Bodies of the Ear, Nose, Airway, and Esophagus.)

## Chapter 349

# ALTERED MENTAL STATUS

Rene J. Forti, MD; Jeffrey R. Avner, MD

Many disease processes act directly or indirectly on the central nervous system (CNS) to cause an alteration in the level of consciousness. Although in severe cases the child seems unresponsive, the initial changes in mental status are often subtle. These changes are recognized by assessing the child’s actions and responses to external and internal stimuli in what is collectively known as *behavior*. Behavior is a combination of a variety of observations, including appearance, level of alertness, speech, affect, mood, thought, and judgment. These actions are child and age specific. For example, apprehension, avoidance, and crankiness may be normal responses of a toddler to a physician’s physical examination, whereas a similar response by an adolescent may be abnormal. Although major changes in behavior are readily apparent, subtle changes are often best appreciated by parents and caregivers.

## DEFINITION OF TERMS

Consciousness is the awareness of self and the environment. Alteration of the level of consciousness usually begins with becoming unaware of self, followed by reduced awareness of the environment, and finally an inability to be aroused. A child who is in a coma is unresponsive to all stimuli, including pain. Although consciousness and coma represent the extremes of mental status, many intermediate levels of consciousness exist. Although specific definitions are given to each stage of consciousness, a progression of symptoms is not an all-or-nothing phenomenon. Rather, a continuum of the levels of consciousness may exist.

Confusion is a state in which a person’s responses are slowed and cognitive abilities are impaired, usually accompanied by some disorientation. Infants and toddlers may exhibit irritability as a sign of confusion. Delirium is a succession of confused and unconnected ideas. Children with delirium are often aggressive, agitated, and combative, with episodes of somnolence and withdrawal. Lethargy is a state of profound slumber in which the child has limited movement and speech. The lethargic child can be awakened with moderate stimuli but then returns to a state of slumber. In stupor, the child seems unresponsive and can be aroused only by repeated, vigorous stimuli. In the vegetative state, the child has lost all cognitive neurologic function, communication, and awareness but may retain some noncognitive functions (eg, eye opening) and a sleep–wake cycle. In coma, the child is totally unresponsive, and the eyes remain closed.

## ETIOLOGY

An altered level of consciousness in children has many causes. The mnemonic AEIOU TIPS is helpful when considering the major categories of illness or injury (see Table 349-1). Although these disorders can occur

**Table 349-1** Mnemonic for Altered Mental Status (AEIOU TIPS)

A	Alcohol, abuse
E	Epilepsy, encephalopathy, electrolyte abnormalities, endocrine
I	Insulin, intussusception, inadequate fluid, ingestion
O	Overdose, oxygen deficiency, occult trauma, obstructed ventriculoperitoneal shunt
U	Uremia
T	Trauma, temperature abnormality, tumor
I	Infection
P	Poisonings, psychiatric, postictal
S	Shock, stroke, space-occupying lesion (intracranial)

**BOX 349-1 Common Causes of Altered Mental Status by Age****INFANT**

- Infection
- Complication of congenital malformation (cardiac or CNS)
- Metabolic
- Inborn error of metabolism
- Seizure
- Nonaccidental trauma/abuse
- Ingestion

**CHILD**

- Infection
- Seizure
- Toxin

- Metabolic
- Nonaccidental trauma/abuse
- Intussusception
- Ingestion

**ADOLESCENT**

- Toxin
- Trauma
- Infection
- Psychiatric
- Seizure
- Ingestion

at any age, certain conditions are more prevalent at certain ages (see Box 349-1). Nontraumatic coma has a bimodal distribution and is most common in infants and toddlers, with a smaller peak in adolescence. Infection of the brain, meninges, or both is the most common cause of altered level of consciousness, accounting for more than one-third of nontraumatic cases. Exposure to or ingestion of toxic substances is the next most common cause. Many medications are brightly colored and taste similar to candy, resulting in accidental ingestion, especially in toddlers. Ingestion by adolescents is often intentional and typically involves over-the-counter medications or psychotropic drugs, such as antidepressants. Commonly ingested

**BOX 349-2 Commonly Ingested Agents That Cause Altered Mental Status**

- Amphetamines
- Anticholinergics
- Anticonvulsants
- Barbiturates
- Benzodiazepines
- Camphor
- Clonidine
- Cocaine
- Dextromethorphan
- Ethanol
- Haloperidol
- Narcotics
- Phenothiazines
- Salicylates
- Selective serotonin reuptake inhibitors
- Tricyclic antidepressants

agents that cause an altered level of consciousness are listed in Box 349-2. Congenital heart and brain malformations typically present in the first few months after birth, but complications from surgical correction of such problems—for example, ventriculoperitoneal shunt obstruction—may occur at any age.

Inborn errors of metabolism, including urea cycle defects, organic acidemias, and specific disorders of amino acid metabolism, typically occur in infancy. Diabetic ketoacidosis is the most common metabolic disorder that can present with an alteration of consciousness. It can occur at any age but is more common in adolescence. An acute confusional state can be seen in autoimmune disease, especially systemic lupus erythematosus. Thrombotic thrombocytopenic purpura is a rare hematologic disorder that can present with confusion and may be associated with systemic lupus erythematosus. Prolonged seizures, anticonvulsive therapy, and the postictal state can alter the level of consciousness at any age.

Although the overall incidence of traumatic and nontraumatic coma is similar, the rate of traumatic injury tends to increase throughout childhood. Head trauma can cause intracerebral, epidural, or subdural bleeding, as well as contusions and diffuse axonal

### BOX 349-3 Differential Diagnosis of Altered Level of Consciousness

#### STRUCTURAL CAUSES

- Cerebral vascular accident
- Cerebral vein thrombosis
- Hydrocephalus
- Intracerebral tumor
- Subdural empyema
- Trauma (intracranial bleeding, diffuse cerebral swelling, shaken baby syndrome)

#### MEDICAL CAUSES (TOXIC-INFECTIOUS-METABOLIC)

- Anoxia
- Autoimmune (systemic lupus erythematosus)
- Diabetic ketoacidosis
- Electrolyte abnormality
- Encephalopathy
- Hematologic (thrombotic thrombocytopenic purpura)
- Hypoglycemia
- Hypothermia or hyperthermia
- Inborn errors of metabolism
- Infection (sepsis)
- Ingestion
- Intussusception
- Meningitis and encephalitis
- Postictal state
- Psychogenic
- Toxin
- Uremia (hemolytic uremic syndrome)

injury. These conditions can lead to cerebral dysfunction, by either primary neuronal damage or the effects of cerebral herniation with brainstem compression. Child abuse should always be considered in any infant with an altered level of consciousness.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a child with altered mental status can be divided into structural (anatomic) causes and medical (toxic, infectious, metabolic) causes (see Box 349-3). This framework is useful in the context of the pathophysiologic factors of maintaining a state of consciousness. Normal mental status requires the combination of thought content (ie, cognition, affect) and a state of arousal. The content is controlled by the cerebral hemispheres, whereas the state of arousal is controlled by the ascending reticular activating system (ARAS). The ARAS, also known as the sleep center, is a core brainstem structure that courses from the medulla to the thalamus. As part of the normal cycling of behavior, consciousness moves from the awake state to drowsiness to sleep. At any time during this transition, sensory impulses may reach the ARAS, leading to an increased awareness and a more awake state. These sensory impulses may be external, such as noise, touch, or smell, or they may be internal, such as headache or abdominal pain.

To maintain a normal level of consciousness, functioning cerebral hemispheres and a functioning ARAS must be present. Defects in either of these components will cause an alteration in mental status. Thus altered mental status can result from depression of both cerebral hemispheres, a localized abnormality of the sleep center, or a global central nervous dysfunction in which both the cerebral cortex and the ARAS are affected. In general, structural causes, such as an epidural hematoma, a cerebral vascular accident, or an intracranial tumor, produce dysfunction in the region of the ARAS. Medical causes, such as meningitis, hypoglycemia, or ingestion of a toxic substance, generally cause dysfunction of both cerebral hemispheres.

The differentiation of structural and medical causes therefore rests on the ability to assess the function of the ARAS. The ARAS is located in the vicinity of several brainstem reflexes, the most important of which is the pupillary light reflex. Pupil size is a balance of parasympathetic and sympathetic inputs. For example, lesions in the midbrain affect the parasympathetic and sympathetic fibers equally, resulting in pupils that are fixed at midsize. Lesions of the pons preferentially affect the descending sympathetic fibers and result in fixed, pinpoint pupils. Importantly, the pupillary reflex is relatively resistant to metabolic insult. Thus preservation of the pupillary response to light, even if sluggish, is one of the most important ways to differentiate structural from medical cause of altered mental status. The cranial nerves that control reflex eye movements and maintain conjugate gaze are also located in the vicinity of the ARAS. Therefore, asymmetrical eye movements, such as a fixed gaze or an inability to abduct an eye, suggest dysfunction in the region of the ARAS, which is often caused by structural problems.

Structural lesions compress or destroy areas of the brainstem and are often characterized by unequal or unreactive pupils, as well as focal neurologic findings. Medical causes produce dysfunction in both cerebral hemispheres but result in preserved pupillary reflexes and nonfocal neurologic findings. Structural causes sometimes occur without focality, such as acute bilateral cerebrovascular disease or early acute hydrocephalus. Similarly, some medical causes, such as hypoglycemia, hypercalcemia, uremia, and a postictal state with Todd paralysis, may be accompanied by focal neurologic findings.

## EVALUATION

Regardless of the underlying cause, patients with an acute change in mental status may exhibit a reduced awareness of self, may have a reduced awareness of the environment, may be agitated with periods of heightened mental activity, or may be unable to be aroused. A complete history and thorough physical examination are crucial in identifying the underlying cause and managing these patients appropriately.

## HISTORY

The history of the manifesting event is often the part of the clinical evaluation with the greatest diagnostic value. Specific detail should be obtained concerning the circumstances of the onset of the neurologic symptoms, including events and actions directly preceding the

change in mental status. Associated symptoms may include weakness, headache, vomiting, dizziness, diplopia, and seizure-like activity. If the alteration in consciousness occurred abruptly, then the physician should consider intracranial hemorrhage, seizure, sudden cardiac arrhythmia, trauma, or ingestion of a toxic substance. A more gradual change in mental status may suggest infection, metabolic abnormality, or a slowly growing intracranial mass. If the altered mental status is preceded by headache (especially on waking), double vision, or nausea and vomiting, then increased intracranial pressure should be suspected. Vomiting and decreased oral intake, especially if accompanied by bloody stool, is seen with intussusception.

A history of trauma is important because it directs the differential diagnosis toward a structural lesion such as an epidural hematoma or cerebral contusion. However, the possibility of nonaccidental trauma, especially if the caregiver's history is inconsistent with the clinical findings, should not be excluded.

Ingestion of toxic substances is a common cause of altered mental status in toddlers and adolescents. In the young child, the history of an accidental exposure is often obtained from the child's caregiver. However, sometimes the ingestion is not witnessed; thus a detailed list of potential poisons to which the child may have access, including prescription and nonprescription medications, should be obtained. It is important to specifically ask about use of alternative and herbal remedies. For example, imported camphor products have been identified as a source of seizures in children in certain ethnic populations that use it as a natural remedy. The adolescent may admit to an intentional overdose, but the history is often obscure or unobtainable. In these cases, interviews with accompanying friends and family members are essential.

The medical history may include an underlying disorder that predisposes the child to a condition that results in altered mental status. A child with diabetes may have ketoacidosis or hypoglycemia. Children with a metabolic disorder or with hepatic or renal failure may develop encephalopathy. An adolescent with systemic lupus erythematosus may have cerebritis.

## PHYSICAL EXAMINATION

A thorough physical examination not only may lead to a probable diagnosis but also may provide a baseline with which future examinations can be compared so as to assess the improvement or deterioration of the child's clinical status. The level of consciousness can be determined by the child's appearance, interactivity, consolability, speech, cry, and gaze. Care must be taken, especially for young children and those with chronic illness, to ascertain the child's baseline state of functioning and responsiveness.

Vital signs are particularly important. Hyperthermia may be present with infection, heatstroke, or certain toxins (eg, cocaine, anticholinergics, phencyclidine). Hypothermia occurs with exposure to cold or with alcohol overdose. Hypertension, bradycardia, and irregular respirations (the Cushing triad) are signs of impending cerebral herniation but only appear late in the course of increasing intracranial pressure. Abnormalities in heart rate and blood pressure

can also occur with fever, pain, arrhythmias, hypovolemia, myocardial injury, and status epilepticus. Abnormal respirations can be seen with pain, hypoxia, acidosis, intoxication, and brainstem lesions. In some cases, the respiratory pattern may be a clue to the level of neurologic dysfunction. Posthyperventilation apnea—a short apnea after deep breathing—occurs with lesions in the cerebral hemispheres. As dysfunction moves rostrally from the midbrain to the medulla, the respiratory pattern progresses from Cheyne-Stokes breathing (crescendo-decrescendo hyperpnea followed by apnea) to central neurogenic hyperventilation (sustained, rapid, deep breathing). Finally, irregular, sporadic, apneustic respiration occurs with low brainstem dysfunction.

The mouth and throat should be examined for signs of airway obstruction causing hypoxia. A budging fontanel and nuchal rigidity are signs of meningitis or meningeal irritation from an intracranial mass. The skin examination can be helpful in identifying hypoxia, anemia, jaundice, carbon monoxide and other poisonings, trauma, and certain infections. Adolescents who are pretending to be unresponsive usually resist opening their eyes, and they avoid hitting themselves when their hand is raised and then allowed to drop to their face. Furthermore, when feigning coma, the eyes close quickly and deliberately after being held open by the examiner, as opposed to true coma, during which the eyes close slowly.

The neurologic examination should be directed at determining whether the underlying diagnosis is of structural or medical origin. The pupillary reflex and extraocular movements may provide essential clues. In pathologic states confined to the cerebral hemispheres, the pupils function normally, unless this state results in herniation. At the level of the diencephalon (thalamus and hypothalamus), pupils are miotic but react to light. With midbrain involvement, pupils may be midposition, irregular, or widely dilated; light reflexes may be absent if oculomotor nerves are involved. Bilateral fixed and dilated pupils indicate massive CNS dysfunction. A unilateral dilated pupil is a common early sign of uncal herniation. Extraocular muscle positions should be noted at rest (deviation may mean seizure activity or structural lesions); spontaneous abnormal eye movements should be identified, and ocular responses to vestibular stimulation should be tested. As with pupillary response, extraocular movements will vary with the level of the lesion. In general, asymmetry is seen with midbrain and upper pons involvement, and lack of extraocular movements is present with lower pons and medullary involvement. Negative doll's eyes—a condition in which the eyes seem painted on the face because the eyes remain stationary with respect to head movement—is seen in comatose patients with a low brainstem lesion.

Not all abnormal pupillary response is because of increased intracranial pressure. Mydriasis can be seen in Horner syndrome and in exposure to certain toxic substances, including anticholinergics, amphetamines, cocaine, and tricyclic antidepressants. Miosis may be caused by cold exposure, opiates, ethanol, barbiturates, cholinergic agents such as organophosphates, and clonidine.

When assessing motor function in patients with an altered mental status, spontaneous movements should be evaluated for signs of hemiparesis that may suggest a structural lesion or uncal herniation. Tone should be assessed for flaccidity and responses to painful stimuli. Patients who are unresponsive may have depressed brainstem function, and those who have increased tone may have diffuse cortical injury. Posturing is a bad sign, and the type of posturing aids in determining the extent of the injury. Decorticate posturing occurs when the patient flexes the arms, wrists, and hands, and adducts the upper extremities while internally rotating and plantar-flexing the lower extremities. This form of posturing occurs as a result of diffuse damage to the cerebral cortex, white matter, and basal ganglia. Decerebrate posturing is when the patient exhibits marked opisthotonus with extended arms and hands, which is usually the result of extensive damage involving the midbrain.

## LABORATORY EVALUATION

In the setting of altered mental status, laboratory testing should focus first on determining life-threatening metabolic derangements and then determination of the underlying cause. Rapid bedside glucose determination can identify hypoglycemia within minutes of clinical evaluation. In addition to being a common cause of altered mental status, hypoglycemia also accompanies many other underlying causes, such as diabetes, metabolic disorders, and sepsis. Calcium and sodium abnormalities can be identified on a serum chemistry panel. Serum bicarbonate and arterial blood gas levels may show acidemia, either as a direct result of an underlying metabolic disorder or as a result of abnormal respiratory effort. Hemoglobin levels can help determine whether anemia is present, and the white blood cell count may be high if the altered mental status results from an infection. Thrombocytopenia is associated with hemolytic uremic syndrome and thrombotic thrombocytopenic purpura. Serum ammonia is an important screening test for many inborn errors of metabolism, although mild hyperammonemia can be a nonspecific finding in children. Other testing to be performed in suspected metabolic abnormalities or when the diagnosis is unsure after initial testing include urine porphyrins, ketone bodies, plasma free fatty acids, carnitine, creatine kinase, lactate, pyruvate, serum amino acids, and urine organic acids.

If ingestion of a toxic substance is considered, then directed drug levels (eg, phenytoin, salicylates) might pinpoint a diagnosis. A qualitative urine toxicology screening can identify a variety of commonly ingested agents, but its usefulness is limited because of the delay until the results become available. Measurement of serum osmolality may be helpful if poisoning with methanol, ethylene glycol, or isopropanol is suspected. Serum co-oximetry is needed for determining carbon monoxide level. If the child is febrile, and infection is a possibility, then blood and urine should be tested for bacterial and viral pathogens. If infection of the cerebrospinal fluid (CSF) is suspected, consider urgent evaluation of the CSF after a mass lesion has been excluded.

Abnormalities on an electrocardiogram (ECG) may be seen in cardiac causes such as myocarditis or

dysrhythmias. However, a normal ECG finding does not rule out these disorders. In addition, many serious drug overdoses have ECG findings. Tricyclic antidepressants cause sodium channel blockage, resulting in primary conduction delays and prolongation of the QRS interval. Ischemic changes on the ECG are seen with cocaine overdose. Neuroleptic overdose (eg, phenothiazines, thioridazine, haloperidol, chlorpromazine) causes QT prolongation.

## Imaging Studies

Although the history and physical examination may provide clues to the underlying diagnosis, neuroimaging of the brain is the fastest, most reliable test to differentiate structural from medical causes of altered mental status. The decision of whether to obtain a computed tomography (CT) scan or a magnetic resonance imaging (MRI) study depends on a variety of factors, including the clinical situation, the stability of the patient, and the availability of the test. MRI uses no ionizing radiation and therefore poses reduced risk to the developing brain of the child. In addition, MRI provides more detail of the soft tissues and better imaging of the brain parenchyma, cerebellum, and brainstem than CT. Therefore, rapid MRI is the preferred imaging modality for the clinically stable child. However, in the setting of an acute change in mental status, a CT scan is usually a readily available, rapid screening test that can identify acute intracranial bleeding, masses, or contusions in emergency situations.

## MANAGEMENT

Management of a child with altered mental status is similar to any emergency condition. The primary objective is to stabilize the child's clinical status and correct any acute life-threatening conditions. Once stabilized, the child should be transported to an acute care facility for additional evaluation and management.

Initial management begins with the ABCs—airway, breathing, and circulation. If the airway is obstructed, which is usually identified by the presence of stridor or an abnormal breathing pattern, then immediate maneuvers to open the airway either by manual positioning or artificial methods (oral airway or endotracheal intubation) should be performed. Oxygen should be routinely administered. Patients with a Glasgow Coma Scale of 8 or less or with respiratory failure should undergo endotracheal intubation. Because many of the causes of an altered mental status require intravenous (IV) fluid or medication, a peripheral IV catheter should be placed. Immediate bedside blood glucose levels should be determined because hypoglycemia is readily identified and easily corrected with administration of IV dextrose. Additional blood tests to help determine the underlying cause should be performed. Empirical administration of naloxone should be considered if the underlying cause is unknown. Naloxone can reverse the depressive cardiorespiratory effects of narcotic ingestion, but it may also be helpful in ingestions of clonidine, dextromethorphan, valproic acid, and captopril. A fluid bolus with normal saline should be administered if signs exist of poor perfusion or hypotension. Acid-base and electrolyte abnormalities, if present, should be corrected.

If the patient has a history of trauma, or if the suspected cause is structural, then intracranial pressure may be high. To control the intracranial pressure, the head should be elevated to 30 degrees and placed in a midline position. Hyperventilation can be a temporizing measure to reduce intracranial pressure. Every effort should be made to stabilize the child as soon as possible and obtain an emergent, rapid MRI or CT scan, as well as a consultation with a neurosurgeon. Obstructive hydrocephalus resulting from an intracranial mass lesion or obstructed ventriculoperitoneal shunt may need to be relieved emergently with a ventriculoperitoneal shunt tap or ventriculostomy.

If a medical cause is suspected, then additional laboratory and radiologic testing may help determine whether the cause is infectious, metabolic, or toxicologic. Fever may indicate an infectious origin, and the child should be provided with IV antibiotics after a blood culture is obtained. If meningitis with altered mental status is suspected, then a lumbar puncture can be performed to help confirm this diagnosis, usually after neuroimaging to rule out increased intracranial pressure. It should be performed if the patient is stable and does not have focal neurologic signs. However, if the child is clinically unstable, then the lumbar puncture should be deferred but without delay in administration of empirical IV antibiotics. If herpes encephalitis is a concern, then empirical acyclovir should be provided. A positive stool guaiac test raises the concern of intussusception, which can be diagnosed by plain-film radiography or ultrasonography and reduced by an air-contrast enema. ECG can identify cardiac dysrhythmias or conduction abnormalities. If unexplained bruising exists, then child abuse should be considered.

When a clear cause cannot be identified, ingestion of a toxic substance should be suspected. Family members should be questioned about the availability of any medication. If possible, the bottle of the medication should be checked and the remaining pills counted to estimate the maximal amount ingested. For some ingestions, antidotes are available. Specialists at the local poison control center can assist in the management of a suspected overdose. Many children will require a dose of activated charcoal, which binds the toxin and limits intestinal absorption.

After stabilization and initial management, the patient should be observed in a monitored setting until mental status improves.

## Chapter 350 ANAPHYLAXIS

Elizabeth Secord, MD; Michael R. Simon, MD

### DEFINITION OF TERMS

Anaphylaxis is a systemic allergic reaction that occurs suddenly after contact with an inciting substance and has been defined as “a serious allergic reaction that is rapid in onset and may cause death.” However, anaphylaxis may also be mild and self-limited. Anaphylaxis is a syndrome that has been classically defined as involving 2 or more organ systems. However, it is now accepted that anaphylaxis can be diagnosed when hypotension alone occurs following exposure to a known or likely allergen. Single organ involvement of the upper airway (larynx, oropharynx, or tongue) is not considered to be anaphylaxis. Severe allergic reactions mediated by IgE have been classically referred to as anaphylaxis while clinically similar events not attributable to IgE were historically referred to as anaphylactoid. The term *anaphylactoid* has been dropped because the clinical syndromes are often indistinguishable and the treatment recommendations are the same regardless of the etiology and pathophysiology. Box 350-1 shows the clinical criteria for anaphylaxis.

### ETIOLOGY

Anaphylactic reactions are mediated through antigen-induced, IgE-mediated mast cell and basophil degranulation. Most of these reactions are induced by foods or medications. Non-IgE-mediated reactions are often the result of direct mast cell degranulation (eg, radiocontrast media or opioids). Some cases of exercise-induced anaphylaxis are also thought to be secondary to direct mast cell degranulation. In anaphylactic reactions to nonsteroidal anti-inflammatory agents, most cases seem to be caused by an inhibition of the cyclooxygenase pathway. Exercise, certain medications (eg, nonsteroidal anti-inflammatory drugs), anesthesia, and alcohol may increase the severity of the response to the allergen. The final common pathway for all of these reactions is mast cell and usually basophil degranulation. When mast cells or basophils are activated, several well-characterized mediators are released (eg, histamine and tryptase). Histamine may account for most of the signs and symptoms. Nevertheless, antihistamines alone cannot prevent or reverse all anaphylactic symptoms. Other mediators such as leukotrienes and platelet activating factor probably contribute to the pathophysiology and symptoms of anaphylactic reactions. Recent work suggests that platelet activating factor is associated with the severity of anaphylactic reactions. Animal studies suggest that nitric oxide production may contribute to the cardiovascular manifestations of the anaphylaxis. Nitric oxide increases the activity of guanyl cyclase, which produces cyclic GMP, which in turn causes vasodilation. Methylene blue is an inhibitor of guanyl cyclase and nitric oxide synthase. Treatment with methylene blue has reversed refractory hypotension in several patients.

**BOX 350-1 Criteria for Anaphylaxis**

Anaphylaxis is highly likely when any 1 of the following 3 criteria are fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin or mucosal tissue (eg, generalized hives, pruritus or flushing, swollen lips, tongue, or uvula) AND AT LEAST 1 OF THE FOLLOWING:
  - A. Respiratory compromise (eg, dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
  - B. Reduced BP or associated symptoms of end-organ dysfunction (eg, hypotension [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly (minutes to several hours) after exposure to a likely allergen:
  - A. Involvement of the skin or mucosal tissue (eg, generalized hives; pruritus or flushing; swollen lips, tongue, or uvula)
  - B. Respiratory compromise (eg, dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
  - C. Reduced BP or associated symptoms (eg, hypotension [collapse], syncope, incontinence)
  - D. Persistent gastrointestinal symptoms (eg, crampy abdominal pain, vomiting)
3. Reduced BP after exposure to known allergen (minutes to several hours)
  - A. Infants and children: low systolic BP (age specific) or  $>30\%$  decrease in systolic BP. Low systolic BP for children is defined as  $<70$  mm Hg from 1 month to 1 year,  $<70$  mm Hg +  $[2 \times \text{age}]$  from 1 to 10 years and  $<90$  mm Hg from 11 to 17 years.
  - B. Adults: systolic BP of  $<90$  mm Hg or  $>30\%$  decrease from that person's baseline.

BP, blood pressure; PEF, peak expiratory flow.

From Sampson HA, Muñoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report—Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol*. 2006;117(2):391–397, with permission from Elsevier.

**EPIDEMIOLOGY**

The incidence of anaphylaxis varies by study but is generally reported as less than 1% and anywhere from 0.04% to 0.4% (40 to 400/100,000/year). It is thought that the incidence is higher than reported because of under-reporting and under-recognition of the syndrome. There is no racial predisposition. In childhood, boys are more likely to suffer from anaphylaxis than girls, and in adult life, women are more likely than men. Atopy is a predisposing factor for food-induced anaphylaxis. Reactions to injected agents tend to be more severe and more rapid than for ingested agents. Risk factors associated with death from anaphylaxis include extremes of age, concomitant cardiac disease, asthma, delay of epinephrine administration, and season of the year.

**SIGNS AND SYMPTOMS**

Ninety percent or more of patients experiencing anaphylactic reactions will report skin manifestations of urticaria, facial swelling (angioedema), pruritus, or

**BOX 350-2 Clinical Signs and Symptoms of Anaphylaxis****CUTANEOUS/SUBCUTANEOUS/MUCOSAL TISSUE**

- Flushing, pruritus, hives (urticaria), angioedema, morbilliform rash, pilor erection
- Pruritus of lips, tongue, and palate; edema of lips, tongue, and uvula
- Periorbital pruritus, erythema, and edema; conjunctival erythema; tearing

**RESPIRATORY**

- **Laryngeal:** pruritus and tightness in the throat; dysphagia; dysphonia and hoarseness; dry staccato cough; stridor
- Sensation of pruritus in the external auditory canals
- **Lung:** shortness of breath, dyspnea, chest tightness, deep cough, and wheezing/bronchospasm (decreased peak expiratory flow)
- **Nose:** pruritus, congestion, rhinorrhea, sneezing

**CARDIOVASCULAR**

- Hypotension
- Feeling of faintness (near-syncope), syncope, altered mental status
- Chest pain, dysrhythmia

**GASTROINTESTINAL**

- Nausea, crampy abdominal pain, vomiting (stringy mucus), diarrhea

**OTHER**

- Urinary urgency, aura of doom, uterine contractions in women

From Sampson HA, Muñoz-Furlong A, Bock SA, et al. Symposium on the definition and management of anaphylaxis: summary report. *J Allergy Clin Immunol*. 2005;115(3):584–591, with permission from Elsevier.

flushing. Difficulty breathing (shortness of breath, chest tightness, or wheezing) is the second most common complaint. Lightheadedness or weakness and palpitations are often reported. Gastrointestinal symptoms such as diarrhea and vomiting may occur. Headache may also be present. Some patients report a sense of impending doom accompanying the onset of anaphylaxis. Although most patients experiencing anaphylaxis develop skin manifestations, the absence of this cutaneous involvement does not rule out anaphylaxis. The onset of symptoms may be related to the route of administration and the rapidity of the systemic absorption of the inciting agent. (See Box 350-2.)

**DIFFERENTIAL DIAGNOSIS****Vasodepressor/Vasovagal Reactions**

Hypotension, pallor, weakness, nausea, and bradycardia are common features of this syndrome, which often occurs after an emotional stressor. Loss of consciousness may also occur. Lack of skin and airway manifestations usually seen in anaphylactic reactions and prompt recovery upon assuming a recumbent position help to differentiate the syndromes. Since

bradycardia occurs in 5% of patients with anaphylaxis, even in the absence of the use of  $\beta$ -adrenergic blockers, it alone does not differentiate anaphylaxis from vasovagal reactions. It is important to remember that anaphylaxis may present with only cardiovascular and no cutaneous signs or symptoms, especially in the context of the administration of a known allergen.

### Panic Attacks

Palpitations, flushing, shortness of breath, and GI symptoms are common with panic attacks. If they are accompanied by vocal cord dysfunction and stridor they may mimic anaphylaxis. Even if these latter symptoms are not accompanied by upper airway involvement, such as stridor, anaphylaxis must be excluded. Patients with panic attacks are unlikely to have wheezing, mucocutaneous manifestations, or hypotension. A comprehensive psychosocial history, physical examination, and a period of monitored observation will help differentiate a panic attack from anaphylaxis.

### Mastocytosis and Mast Cell Activation Syndrome

Anaphylaxis may occur in patients with systemic mastocytosis and mast cell activation syndromes, because these mast cell lesions bind IgE and release histamine and other mast cell mediators. Urticaria pigmentosa, the most typical skin lesions of mastocytosis, may suggest the diagnosis. If the lesions are primarily internal, a higher level of suspicion will be necessary to make the diagnosis. Tests, including total serum tryptase, urinary histamine metabolites, and genetic testing for mastocytosis, may be necessary to diagnose mastocytosis in patients with anaphylaxis. Serum/plasma concentrations of total tryptase are acutely elevated in patients with anaphylaxis, while total tryptase is increased in patients with mastocytosis even when they are not acutely ill.

### Hypoglycemia

Flushing can occur with hypoglycemia, mimicking an early allergic skin reaction. This may be associated with tachycardia, anxiety, diaphoresis, and lightheadedness.

## EVALUATION

### Relevant History

Food-induced anaphylaxis is more common in children than in adults. A history of recent food ingestion should always be sought. Most anaphylactic reactions to foods occur in the first 2 hours after eating, with most occurring within the first 30 minutes. There are reports of reactions beginning up to several hours later. Gastrointestinal symptoms such as nausea, vomiting, crampy abdominal pain, and diarrhea are more likely in patients with food-induced anaphylaxis. Peanuts, tree nuts, fish, and shellfish account for most anaphylactic reactions to foods, with peanut being the most common (up to 62% of cases). These foods usually are responsible for lifelong allergies in affected persons, and children are not likely to “outgrow” these reactions. Milk, soy, egg, and wheat also are responsible for severe allergic reactions in infants and toddlers, but unlike reactions to peanuts, tree nuts, fish, and shellfish, most children become tolerant to milk and soy in particular, and to eggs in some but not all cases. In some patients with severe food allergy,

inhalation of the offending antigen is sufficient to lead to a reaction in a sensitized individual. Some with apparent idiopathic anaphylaxis may actually be reacting to inhalation of pollen to which they are exquisitely sensitive.

Injected venoms from *Hymenoptera* insect sting (ie, bees, yellow jackets, hornets, wasps, fire ants) can cause anaphylaxis in sensitized individuals. From 0.5% to 3.0% of the population experiences a systemic reaction after *Hymenoptera* stings. History of exposure to particular insects may be important later if venom injection immunotherapy is to be considered. In the case of bee sting it is important to remove the stinger early to avoid further venom injection. Identification of the wound or stinger helps identify the species. Bees (and very rarely yellow jackets) leave a stinger in the skin while other *Hymenoptera* do not.

Medications are another common cause of anaphylactic reactions. Penicillin is the most common cause. Aspirin and other nonsteroidal anti-inflammatory agents may also induce reactions. Drugs that are administered intravenously or intramuscularly are absorbed more rapidly and are associated with more severe reactions. Anaphylactic reactions occurring in hospitalized patients are most commonly caused by medications, latex, and, rarely, anesthetics. Latex allergy has become less common.

Exercise-induced anaphylaxis usually occurs in teenagers and young adults. It may occur unpredictably and is often difficult to diagnose. There may be a prodrome of flushing and abdominal pain followed by collapse during exercise. Some cases of exercise-induced anaphylaxis occur only after ingestion of foods that cross-react with pollens (eg, melons/ragweed or apples/birch). The combination of exercise with food ingestion seems to be necessary for the event in this subgroup. Some also have exercised-induced anaphylaxis after ingestion of any food combined with exercise. This variability may make exercised-induced anaphylaxis difficult to diagnose. Exercise-induced anaphylaxis may follow episodes of exercise-induced urticaria.

Exercise, certain medications (eg, nonsteroidal anti-inflammatory drugs), anesthesia, and alcohol may affect the severity of the response to allergen.

### Physical Examination

#### Respiratory

Bronchospasm with wheezing is common. Edema of the airway may cause stridor or hoarseness. Cyanosis may occur. Upper respiratory findings include nasal congestion, rhinorrhea, sneezing, and lingual and pharyngeal edema.

#### Skin

Urticaria, angioedema, or flushing is evident in approximately 90% of cases.

#### Cardiovascular

Tachycardia is a common finding resulting from the adrenergic response to decreased intravascular volume or histamine activity through the H<sub>2</sub> receptor. Hypotension may then occur and be followed by anaphylactic shock. Postural hypotension may precede frank hypotension.

### Ocular

Tearing, conjunctival erythema, and edema (chemosis) may be present.

### Laboratory Testing

The history and clinical assessment are far more important in the initial evaluation of anaphylaxis than laboratory testing. Histamine, which mediates many of the symptoms in anaphylaxis, has a very short half-life. Histamine plasma concentrations peak within 5 to 60 minutes after an anaphylactic event, so histamine is not a reliable or useful marker in most instances. However, histamine metabolites in the urine may be clinically useful in the diagnosis of systemic mastocytosis. Specific IgE (skin prick tests for specific allergens or serum antigen specific IgE tests) may be useful to help determine the cause of the reaction. These tests may not be valid at the time of presentation because the specific IgE may no longer be present in the skin or serum. It may have been consumed in the allergic reaction. For this reason, testing for specific IgE may not reliably be done for up to 6 weeks after the incident. If there is uncertainty as to whether the reaction is anaphylaxis and the incident has occurred within the last 1 to 2 hours, serum tryptase may be useful in establishing the diagnosis. It may remain elevated in the blood for up to 6 hours after the event. Serum tryptase concentrations that are 135% increased from a patient's baseline level at 2 to 5 hours after exposure suggest the diagnosis of anaphylaxis even if the absolute value is below the upper limit of normal. The baseline level should be determined more than 3 days after the event and more than 1 day after resolution of symptoms. Tryptase is measurable up to several days later in serum samples that have been refrigerated. This allows for determination of tryptase after the fact from samples that were obtained for other laboratory studies. Pulse oximetry or arterial blood gas determinations may be appropriate in patients with cyanosis or respiratory compromise.

### Imaging

Imaging is not an important modality in evaluating anaphylaxis.

### Management

**Epinephrine** injected in the lateral thigh muscle is the most important initial treatment for anaphylaxis. Epinephrine should be administered while the assessment is being made. The dose for children is 0.01 mg/kg of a 1:1,000 solution (0.01 mL/kg up to a maximum of 0.5 mL) intramuscularly, preferably in the outer thigh. The dose may be repeated as needed every 5 minutes. It may be necessary to administer epinephrine as a 1:10,000 solution intravenously in the event of severe hypotension with peripheral vasoconstriction resulting from severely decreased intravascular volume. A common factor associated with fatal anaphylaxis is delay in epinephrine administration.

**Fluid replacement** may be necessary if hypotension from increased vascular permeability is present. Children should receive up to 30 mL/kg of crystalloid solution in the first hour to treat hypotension, although additional IV fluids, usually in boluses of 20 mL/kg,

may be necessary to treat anaphylactic shock. Adults often require 1 to 2 liters over the first hour.

The airway should be secured, and respiratory rate, blood pressure, and pulse rate should be obtained and monitored. The patient should be placed in the supine position with feet elevated if the blood pressure is decreased. A compromise regarding the recumbent position may have to be made to allow adequate air exchange if the patient is wheezing. Oxygen should be administered.

Although not widely appreciated as a treatment adjunct, a tourniquet that is applied on an extremity proximal to a *Hymenoptera* sting or medication injection will slow systemic absorption of antigen and anaphylactic mediators. This is especially valuable when medication is not immediately available.

### Intravenous Vasopressors

In severe refractory hypotension (failure to maintain systolic blood pressure above 90 mm Hg), continuous intravenous infusions of dopamine, norepinephrine, or epinephrine may be required. Vasopressin may also be used in patients who do not respond to epinephrine or these other pressors. The vasopressin infusion may be started at 0.0003 UI/kg/min.

In cases in which the patient is on a beta blocker (more common in adults than children) the patient may be refractory to standard therapy and have relapsing symptoms or hypotension and bradycardia that have not responded to treatment. These patients are at increased risk for death from anaphylaxis. Glucagon is recommended when the patient has been on a beta blocker, and should be considered in cases of anaphylaxis with refractory hypotension even without a clear history of  $\beta$ -blockade. The recommended dosing of glucagon is 1 to 5 mg (20–30 mcg/kg, maximum dose 1 mg in children), administered intravenously over 5 minutes and followed by an infusion (5–15 mcg/min) titrated to clinical response.

Methylene blue, which is used to treat methemoglobinemia, has been successfully used to treat patients with severe anaphylactic hypotension. The dose is a 1.5 to 2 mg/kg bolus of 4% methylene blue. Then a 1- to 2-hour continuous infusion of 1.5 mg/kg diluted in 5% dextrose in water is administered.

### Nebulized $\beta_2$ Agonists

Inhaled albuterol may be used for wheezing that is not responsive to parenteral epinephrine.

### Antihistamines

H<sub>1</sub> antihistamines have a slower onset of action than epinephrine, have little effect on blood pressure (unless combined with an H<sub>2</sub> antagonist), and should be considered a second-line treatment for anaphylaxis.

H<sub>1</sub> antihistamines are often given to relieve pruritus, urticaria, and angioedema. It is very important, however, to remember that these drugs are not effective for treating life-threatening symptoms. They do not replace epinephrine. H<sub>1</sub> antihistamines are often used mistakenly as the primary treatment for anaphylaxis. First-generation H<sub>1</sub> antihistamines commonly cause drowsiness and may impair the patient's ability to relate the progress or resolution of his or her symptoms.

The intravenous administration of the combination of an H<sub>1</sub> antihistamine (eg, diphenhydramine 25–50 mg) with the H<sub>2</sub> blocker cimetidine (300–400 mg intravenously by piggyback infusion) has been demonstrated to block both the cardiac and peripheral vascular effects of histamine. Ranitidine may also be used.

### Corticosteroids

The use of adrenal corticosteroids (eg, methylprednisolone) is recommended based on their efficacy in asthma and their beneficial effect in decreasing vascular permeability. The data, however, do not indicate that use of corticosteroids prevents biphasic reactions. Patients with biphasic reactions often experience the recurrence of their initial signs and symptoms several hours following their apparent resolution.

If given, the dosing of intravenous corticosteroids should be equivalent to 1.0 to 2.0 mg/kg per dose of methylprednisolone every 6 hours. Oral administration of prednisone at 1.0 mg/kg, up to 50 mg, might be sufficient for milder attacks. Box 350-3 provides further details on recommended drugs and dosages for management of anaphylaxis in children.

### Discharge

Patients having had anaphylaxis should be discharged with an epinephrine autoinjector. They must be taught

how and when to use the device and must understand that it should be available at home, school, work, or anywhere the patient travels. The patient needs to understand that the devices have expiration dates and should be renewed.

A referral to a board-certified allergist is recommended to identify the etiology of the reaction and to provide education on avoidance of subsequent reactions. This is particularly important for reactions to food, insect stings, and medication. A “medic alert” bracelet should be prescribed. Venom injection immunotherapy is indicated for treatment of moderate to severe *Hymenoptera* sting anaphylaxis. In cases of exercise-induced anaphylaxis, patients should be advised never to exercise or swim alone.

### Clinical Course

Anaphylaxis may be uniphasic, biphasic, or protracted. Biphasic reactions occur in 4% to 20% of patients with anaphylaxis. Patients with biphasic reactions often experience the recurrence of their initial signs and symptoms several hours following their apparent resolution. This biphasic response usually occurs within 8 hours of the initial reaction, but can occur up to 72 hours later.

## BOX 350-3 Drugs and Dosages

**Epinephrine** (aqueous) 1:1,000 concentration: 0.01 mg/kg, maximum dose 0.5 mg (0.5 mL)

### For hypotension refractory to epinephrine

- Vasopressin started at 0.0003 U/kg/min
- Levarterenol 0.5–1.0 mcg/min, titrated to maintain blood pressure
- Dobutamine 2–20 mcg/kg/min, titrated to maintain blood pressure

### For β-Blockade

- Glucagon 20–30 mcg/kg, maximum dose 1 mg in children intravenously over 5 minutes, then 5–15 mcg/min titrated to clinical response vs 50 micrograms/kg intravenous loading dose, followed by a continuous infusion of 1–15 mcg/hr, titrated to patient vs 50–150 mcg/kg bolus over 1 minute, then 1–5 mg/hr

### For shock

- Methylene blue, 4%: 1.5–2 mg/kg bolus, then a 1–2 hour continuous infusion of 1.5 mg/kg diluted in 5% D<sub>5</sub>W

### Antihistamines: use H<sub>1</sub> together with H<sub>2</sub> blocker

- Diphenhydramine 1–1.5 mg/kg, maximum dose 75 mg

### H<sub>2</sub> receptor blockers

- Ranitidine 1–2 mg/kg, maximum dose 150 mg
- Cimetidine 20–40 mg/kg/day divided q6hr IV/IM/PO
- Neonates (<28 days old): 5–20 mg/kg/day divided q8–12hr IV/IM/PO
- Infants: 10–20 mg/kg/day divided q6–12hr IV/IM/PO

### Adrenal corticosteroids

- Methylprednisolone 1–2 mg/kg up to 125 mg
- Prednisone 1–2 mg/kg up to 75 mg

IM, intramuscular; IV, intravenous; PO, by mouth.

### WHEN TO REFER

All patients with anaphylaxis and anaphylactoid reactions should be referred to an allergist for identification of the responsible agent and for patient education.

### WHEN TO ADMIT

A reasonable length of time to consider observing the postanaphylactic patient is 4 to 6 hours for patients with mild to moderate anaphylaxis. Prolonged observation times (8–24 hours) or hospital admission are appropriate for patients with severe reactions (hypoxemia, airway edema, or shock) or refractory symptoms. More caution should be used in patients with a history of asthma or wheezing.

## Chapter 351

# APPENDICITIS

R. Scott Strahlman, MD

Abdominal pain is a common chief complaint in the pediatric population. The pediatric primary care physician is crucial in the initial evaluation, diagnosis, and management of abdominal pain and is often the first person to suspect appendicitis. Although appendicitis is a surgical emergency, a physician's high index of suspicion can be the driving force that leads to an appropriate, timely appendectomy. Prompt diagnosis and preoperative management help reduce the high morbidity associated with a perforated appendix.

**DEFINITIONS**

Appendicitis is an inflammation of the vermiform appendix, a small appendage arising from the cecum. Vermiform means *worm shaped* and accurately describes the appearance of this structure. Appendicitis is the most common cause of an acute surgical abdomen in childhood. Although the exact incidence is unknown, appendicitis is rare in early childhood and more common after age 10 years. Boys and girls are affected equally before puberty, but after age 15 years, twice as many boys are affected as girls. An increased incidence in the spring and autumn months has also been observed. In addition, appendicitis is more common in children who have a family history of appendicitis. Whether this tendency is genetic or diet related is unclear; the risk for appendicitis may be reduced with a high-fiber diet.

**ETIOLOGY AND PATHOPHYSIOLOGY**

Appendicitis is always initiated by obstruction of the appendiceal lumen, usually by a fecalith or by lymphoid hyperplasia. In rare cases, a parasite, tumor, or foreign body may obstruct the lumen. inspissated secretions of cystic fibrosis may also obstruct the appendiceal lumen (thus, although rare, the initial presentation of cystic fibrosis may be appendicitis). As secretions accumulate within the obstructed appendix, it becomes distended, and the appendiceal wall stretches. Continued distention causes ischemia and inflammation of the appendix, leading to irritation of the adjacent somatic peritoneum.

Clinically, the initial distention of the appendix produces a dull, steady periumbilical pain. After 4 to 6 hours, this pain often shifts to the right lower quadrant as local peritoneal inflammation develops. Without surgical intervention, the appendix will eventually rupture, causing peritonitis. The incidence of rupture increases dramatically 24 to 36 hours after the onset of abdominal pain. Organisms cultured from the peritoneal cavity after perforation include both aerobic and anaerobic bacteria. The most common aerobic bacteria are *Escherichia coli*, *Staphylococcus aureus*, and *Enterococcus* spp. organisms. Common anaerobes include *Bacteroides* and *Clostridium* spp.

**EVALUATION****History**

A thorough history is invaluable in differentiating appendicitis from other disorders; an important component of this history is pain. The onset of symptoms is often heralded by a dull, steady periumbilical pain. The pain is thought to be caused by acute appendicitis if it awakens the patient from sleep. Anorexia is a consistent, but not invariable, finding. One or 2 episodes of vomiting may follow; however, these episodes essentially never precede the pain. After 4 to 6 hours, the pain commonly migrates to the right lower quadrant. Given the many variations in the location of the appendix, however, the location of abdominal pain may vary. Bowel habits usually do not change. Although the child may have a low-grade fever, the temperature is rarely above 37.9°C

(100.3°F) before perforation. Even if the clinical picture suggests appendicitis but does not convince the physician that appendicitis is the problem, referral for surgical evaluation would be best. Because an appendix rarely perforates within 24 hours of the onset of pain, a period of observation can safely differentiate a potential surgical condition from a non-surgical one. It is important, however, to be aware that perforation of the appendix may be associated with an initial lessening in the pain, only to be followed by a worsening of symptoms within a few hours.

### Physical Examination

As always, a gentle, nonthreatening approach is most effective during the physical examination. The physician should assess for peritoneal signs such as pain on walking or coughing. If the patient can jump up on the examining table, then the patient does not usually have appendicitis. Patients may be most comfortable lying supine with their legs flexed. Abdominal tenderness is always present and is often greatest at the McBurney point (two-thirds of the distance on a direct line from the umbilicus to the anterosuperior iliac spine). Rebound tenderness of the abdomen, especially referred to the right lower quadrant, is common, as is hyperesthesia of the skin overlying the painful area. (In infants, tenderness is present diffusely over the abdomen because they are rarely seen before perforation.) Pain in the right lower quadrant may be accentuated when the inflamed appendix is located retroceally by (1) placing the patient in the left decubitus position and extending the right leg at the hip, thereby placing tension on the right psoas muscle, the origins of which underlie the appendix (psoas sign); and (2) placing the patient supine and internally rotating the flexed right hip, thereby extending the right internal obturator muscle, the origins of which also underlie the appendix (obturator sign). When the inflamed appendix is located anteriorly, pain in the right lower quadrant may be accentuated when the child is asked to sit up from the supine position while pressure is placed against the forehead. Bowel sounds may be diminished or hyperactive. A rectal examination will often facilitate making the diagnosis by revealing right-sided tenderness. Examination of the lungs is important to rule out a right lower lobe pneumonia that may generate referred pain to the right lower quadrant of the abdomen. A pelvic examination is indicated for any adolescent girl who has abdominal pain to rule out gynecologic conditions.

### Laboratory Testing

The only essential laboratory studies are a blood count and urinalysis. Appendicitis, without perforation, has a characteristic blood count; the white blood cell count is most often in the range of 10,000 to 20,000/mcL, with a slight increase in the number of neutrophils, particularly young forms. The blood count may help rule out viral infection and other processes that do not increase the white blood cell count. The erythrocyte sedimentation rate is usually normal and, if elevated, may suggest such alternative diagnoses as inflammatory bowel disease. Urinalysis is performed to rule out urinary tract infection or diabetic ketoacidosis as a cause of

the abdominal pain. Some hospitals are using the laboratory markers of a white blood cell count above 12,000/mcL and a C-reactive protein above 3 mg/dL to indicate possible appendicitis.

### Imaging

If the diagnosis is in doubt, then imaging studies can provide important information. Abdominal radiographs are occasionally helpful. Radiographic features that suggest appendicitis include a calcified appendicolith or an air-filled appendix, although the absence of abnormalities does not rule out the diagnosis. Recently, ultrasonography and computed tomography have been used to establish the diagnosis in equivocal cases. In 1 study, the selective use of computed tomography and ultrasound decreased the incidence of perforated appendicitis from 35.4% to 15.5% and decreased the rate of removing a normal appendix (a negative appendectomy) from 14.7% to 4.1%. When available, consultation with a pediatric surgeon may minimize the need for imaging studies while maintaining low rates of perforation and negative appendectomy.

Some physicians use clinical decision rules to aid in the diagnosis of appendicitis and to avoid overuse of imaging studies. A white blood cell count of greater than 10,000/mcL and the presence of rebound abdominal tenderness are highly suggestive of appendicitis and warrant a prompt surgical evaluation without the need for imaging studies. A white blood cell count of less than 6,750/mcL with the absence of nausea and of right lower quadrant tenderness are highly associated with the absence of appendicitis. Careful observation without imaging studies can be considered in such cases.

The typical progression of signs and symptoms in appendicitis may be summarized as follows: periumbilical abdominal pain followed by nausea, vomiting, and localization of the pain to the right lower quadrant. Low-grade fever, direct tenderness to palpation in the right lower quadrant and indirect tenderness referred to the right lower quadrant, right-sided tenderness on rectal examination, and a mild leukocytosis often accompany these symptoms.

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis of appendicitis, which is the same as the differential diagnosis of acute abdominal pain, is extensive (Box 351-1). Gastroenteritis can be differentiated from appendicitis based on a generally benign abdominal examination in the former condition. Vomiting and diarrhea usually occur before the onset of pain, not afterward, as is the case in appendicitis. Constipation can often seem to be appendicitis; however, this pain is usually diffuse, not localized to the right lower quadrant, and the patient often has a history of constipation. An abdominal flat-plate radiograph can help in the diagnosis, and a small Fleet enema is often both diagnostic and therapeutic.

The typical progression of signs and symptoms in appendicitis is probably the most helpful in differentiating it from other diagnoses—periumbilical abdominal pain followed by nausea, vomiting, and localization of the pain to the right lower quadrant. Low-grade fever, direct tenderness to palpation in

**BOX 351-1 Differential Diagnosis of Appendicitis**

<b>COMMON CONDITIONS</b>	Ruptured ectopic pregnancy
Gastroenteritis	Dysmenorrhea
Constipation	Mittelschmerz
<b>MEDICAL PROBLEMS</b>	Ruptured corpus luteum cyst
Urinary tract infection	<b>UNUSUAL CONDITIONS</b>
Diabetic ketoacidosis	Henoch-Schönlein purpura
Sickle cell crisis	Hemolytic uremic syndrome
Right lower lobe pneumonia	Rocky Mountain spotted fever
Primary peritonitis	<b>SURGICAL EMERGENCIES</b>
Inflammatory bowel disease	Meckel diverticulitis
<b>GYNECOLOGIC PROBLEMS</b>	Intestinal adhesions
Pelvic inflammatory disease	Intussusception
Ovarian torsion	Necrotizing enterocolitis

the right lower quadrant and indirect tenderness referred to the right lower quadrant, right-sided tenderness on rectal examination, and a mild leukocytosis often accompany these symptoms.

An appropriate initial evaluation can rule out the following nonsurgical conditions in a patient who has abdominal pain: urinary tract infection, diabetic ketoacidosis, sickle cell crisis, right lower lobe pneumonia with referred pain, nephrotic syndrome with primary peritonitis, and inflammatory bowel disease. Gynecologic disorders can be ruled out based on the history, a pelvic examination, and appropriate diagnostic studies; pelvic inflammatory disease, ovarian torsion, ectopic pregnancy, dysmenorrhea, and Mittelschmerz can all mimic appendicitis.

Unusual conditions such as Henoch-Schönlein purpura and hemolytic uremic syndrome may be indistinguishable from appendicitis. Even Rocky Mountain spotted fever can mimic appendicitis. Surgical emergencies that mimic appendicitis (see Box 351-1) can be ruled out only in the operating room.

### APPENDICITIS IN INFANTS

Appendicitis in the first 2 years of life is rare, accounting for fewer than 2% of all childhood cases. The morbidity is high, however, and the incidence of perforation approaches 100%. Therefore, appendicitis must be considered in any infant thought to have abdominal pain. The presenting symptoms consist of vomiting and fever, and the baby may appear to be colicky. Physical examination shows abdominal distention with diffuse tenderness. Abdominal radiographs can be diagnostically helpful in a neonate by showing an appendicolith, free peritoneal fluid, bowel wall edema, or, rarely, free air. With a high index of suspicion, surgery must be performed immediately to prevent or manage perforation, with its high morbidity.

### MANAGEMENT

Once the diagnosis is made, referral for surgery should be made immediately. Nothing is given by mouth, and a nasogastric tube is inserted and placed on low suction if the child is vomiting. Intravenous hydration is started, and fever may be controlled with acetaminophen given by rectum. Broad-spectrum antibiotics (eg, ampicillin, gentamicin, and clindamycin or a cephalosporin) are administered intravenously before surgery. Antibiotics have been shown to reduce morbidity, even in nonperforated cases. An appendectomy is performed as soon as the patient's condition has been stabilized. Laparoscopic appendectomy is being performed at most institutions.

For patients who have symptoms for 5 days or longer and a palpable mass consistent with an appendiceal abscess, many surgeons initially prefer nonsurgical management. The patient is treated with broad-spectrum antibiotics for 14 days (initiated in the hospital and completed at home) if the child's clinical condition allows and, barring interim complications, returns in 6 to 8 weeks for an elective appendectomy. This approach lowers the incidence of diffuse peritonitis and the associated complications precipitated by surgical manipulation during the acute inflammatory stages of the disease.

### PROGNOSIS

For uncomplicated appendicitis treated with prompt surgical intervention, the mortality rate is less than 1%, and long-term morbidity is primarily the risk for adhesive small bowel obstruction. The average hospital stay is about 2 days. Although a ruptured appendix increases the risk for mortality (with most of the increase occurring in infants or in older children with delayed diagnosis who develop sepsis), perforation significantly extends the average hospital stay. Complications that increase morbidity include peritonitis, postoperative abscesses, and prolonged ileus. Perforation also significantly increases the risk for postoperative adhesive small bowel obstruction. In women, although infertility was thought to be a possible long-term complication of a ruptured appendix, recent studies have shown this not to be the case.

The incidence of perforated appendicitis exceeds 30%, a disconcertingly high figure, despite increasing use of radiographic imaging. A higher index of suspicion on the part of families and pediatricians may lead to earlier diagnosis of the condition and reduce the incidence of appendiceal perforation and its morbid complications.

#### WHEN TO REFER

- Refer to surgery immediately whenever appendicitis is suspected.

#### WHEN TO ADMIT

- Hospitalize for inpatient observation if the diagnosis cannot be excluded and for appendectomy if the diagnosis of appendicitis is made.

## Chapter 352

# CROUP (ACUTE LARYNGOTRACHEOBRONCHITIS)

Caroline Breese Hall,<sup>†</sup> MD; William J. Hall, MD, MACP

## DEFINITION

Viral croup (acute laryngotracheobronchitis) is an age-specific viral syndrome characterized by acute laryngeal and subglottic swelling, resulting in hoarseness, cough, respiratory distress, and inspiratory stridor. Inflammation at the subglottic area is apt to cause marked airflow obstruction because the anatomy of the cricoid and thyroid cartilage make this area the narrowest and the least distensible part of the larynx. Inflammation, however, commonly affects the conducting airways at all levels.

This syndrome, recognized and respected by physicians for centuries, inherited its name, croup, from the Anglo-Saxon word *kropan*, or from an old Scottish word *roup*, which meant to cry out in a hoarse voice. *Spasmodic croup* is a term sometimes used to denote afebrile episodes of croup that may be recurrent. Airway hyperreactivity resulting from allergens may play a role in predisposing some children to repetitive bouts of croup. In the past, diphtheria was commonly referred to as *membranous croup*, which, until the twentieth century, was considered the cause of most croup cases. Occasionally, *membranous croup* is still used for croup-like cases caused by bacteria.

## ETIOLOGY AND EPIDEMIOLOGY

### Viral Agents

A variety of agents may be associated with croup. The parainfluenza viruses are identified most often as causing this disease, especially parainfluenza virus type 1. In an 11-year study of croup in a private practice in Chapel Hill, North Carolina, the parainfluenza viruses constituted 75% of viral isolates obtained from children who had croup, and 65% of the parainfluenza viral isolates were parainfluenza virus type 1. Among 144 children presenting with inspiratory stridor to emergency departments in Helsinki, the parainfluenza viruses accounted for 42% of the cases, and parainfluenza virus 1 was the single most often identified agent (31%).

However, among hospitalized children, a recent multicenter population-based study showed that parainfluenza viruses 1 and 2 were almost equal in frequency.

Influenza viruses A and B and respiratory syncytial virus (RSV) are usually the next most often identified agents. Influenza virus, especially influenza A virus, has been associated with croup that is more severe than the usual cases associated with the more common parainfluenza viruses. With the increasing use of molecular diagnostic techniques, such as reverse transcriptase polymerase chain reaction (RT-PCR), many more viruses have been detected in children with croup. Rhinoviruses, enteroviruses, and bocaviruses have been detected in approximately 10% of children presenting with croup, and adenovirus, human metapneumoviruses, *M pneumoniae*, and human coronaviruses have been detected occasionally, in 1% to 2% of specimens from croup cases. However, 1 type of human coronavirus, NL63, seems to cause infection that often manifests as croup. A large prospective German study identified human coronavirus NL63 in 5% of children younger than 3 years, and it was strongly associated with croup. This agent was more often identified during the winter than at other times of the year and among ambulatory children more than among hospitalized children.

Many of these agents have been identified as coinfections, which leads to diagnostic confusion. Rhinoviruses are detected concurrently with another virus especially often. Two-thirds of the specimens with rhinoviruses obtained from children presenting with croup to Finnish emergency departments had another respiratory agent concurrently identified by RT-PCR.

In the United States, measles was once a major cause of croup cases, which were often severe. Measles should still be considered in inadequately immunized populations.

Although the number of croup-related visits to emergency departments has increased in recent years, the number of hospital admissions from croup has been declining since the 1990s. This decline is most likely explained by the wider use of therapeutic modalities, primarily corticosteroids and nebulized epinephrine, which may be administered in the outpatient setting.

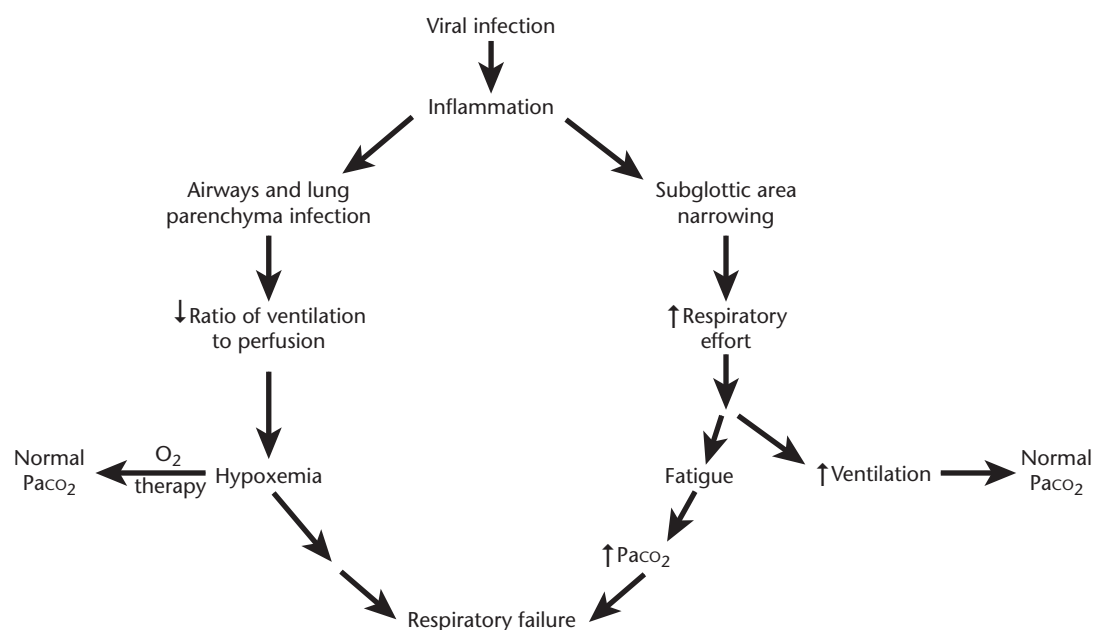

### Seasonal Occurrence

The singular seasonal patterns of croup cases correlate closely with activity of the major viral agents causing the syndrome, predominantly the parainfluenza viruses (Table 352-1). Parainfluenza virus type 1, the most common cause of croup, has the distinctive pattern of producing epidemics of croup and other associated respiratory illnesses every other year in the autumn. In a long-term surveillance program conducted in Monroe County surrounding Rochester, New York, the parainfluenza viruses constituted approximately 17% of all the viral isolates obtained from outpatients in private practices and for 67% of the isolates from children who had croup. Smaller peaks of croup are associated with outbreaks of parainfluenza virus types 2 and 3, influenza, and RSV. Although the proportion of RSV infections that are exhibited as croup is relatively small (approximately 5%), RSV is associated with up to 11% of all croup cases.

<sup>†</sup>Deceased

**Table 352-1** Agents and Seasonal Patterns of Viral Croup in the United States

AGENT	SEASONAL PATTERN
<b>MOST COMMON</b>	
Parainfluenza type 1	Biennial epidemics in the fall
Parainfluenza type 2	Variable fall outbreaks, commonly biennial concurrent with parainfluenza type 1 outbreaks
Parainfluenza type 3	Annual spring outbreaks, extending into summer and early fall
<b>LESS COMMON</b>	
Influenza A	Epidemic, winter
Influenza B	Epidemic, winter
Respiratory syncytial virus (RSV)	Epidemic, winter and spring
Human metapneumovirus	Winter and spring
Adenoviruses	All year
Picornaviruses	Fall, spring–summer
Coronaviruses	Winter and spring

**Figure 352-1** Physiologic abnormalities in viral croup. Viral infection of the subglottic area produces inflammation and obstruction, resulting in an initial decrease in the child's tidal volume. To maintain an adequate alveolar ventilation, the child increases the respiratory rate. With greater degrees of obstruction, however, the work of breathing may increase such that the child can no longer compensate by the increased respiratory effort. The ensuing decrease in tidal volume and respiratory rate may then result in hypercapnia and secondary hypoxemia.

### Host Factors Affecting Croup

Epidemiologic observations indicate that both the predilection for acquiring croup and for developing more severe illness are related to certain characteristics of the affected child. Boys seem more susceptible to developing croup than girls. Among both hospitalized and ambulatory croup cases, the ratio of boys to girls is approximately 2:1. Furthermore, although essentially all children acquire infection with the common respiratory viruses, such as the parainfluenza viruses and RSV, only a minority will manifest primary infection as croup. Also, some children will have multiple episodes of croup caused by different viruses.

Most striking is the affect of age on the occurrence and manifestations of croup. Croup occurs primarily in children between 3 months and 3 years of age and accounts for approximately 10% to 15% of respiratory

tract disease in children. The peak incidence of croup occurs between 6 and 24 months of age among both ambulatory and hospitalized cases. The age predilection of viral croup can be explained partly by the anatomic features of the airway of young children. Their small airways are particularly prone to obstruction from inflammation of the lining membranes. The subglottic trachea of a young child is relatively smaller and also more pliable than that of an older individual. The narrowing that occurs with inspiratory effort, therefore, may be exaggerated in a young child with croup. In addition, obstruction above the subglottic area, which occurs with nasal congestion, increases the collapsing force, and an increased respiratory rate associated with crying or anxiety may compromise the child's ventilation further (Figure 352-1).

Other host factors (eg, genetic and immunologic mechanisms), as yet poorly defined, are likely to contribute to the development and severity of croup. Atopy or hyperreactivity of the airways has been suggested in some studies as playing a role in the development of spasmodic and recurrent croup by the higher incidence of a family history of allergy and positive skin tests for allergens in such children. However, other studies have failed to show children with a single episode compared to those with recurrent episodes to be significantly different in their or their family's history of atopy.

The role in croup of genetic and anatomic host factors is suggested by the prospective Tucson studies of lower respiratory tract disease. Children were enrolled at birth and monitored through 13 years of age with periodic pulmonary function tests and markers of atopy. Children who had croup associated with wheezing had significantly lower levels of indices of intrapulmonary airway function as infants, before any lower respiratory tract illness, and an increased risk of persistent wheezing in later life. In contrast, premorbid inspiratory resistance was significantly higher among children who subsequently developed croup without wheezing compared with those who developed croup with wheezing or who never developed croup.

## DIFFERENTIAL DIAGNOSIS

Many entities may cause stridor and mimic viral croup (Box 352-1) with an important differentiating factor being the relatively acute onset of croup. However, most important and urgent to consider in the differential diagnosis are the 2 bacterial causes of stridor: bacterial tracheitis and epiglottitis. Although these entities currently are uncommon, they may be fatal without immediate therapy. Since the conjugated *Haemophilus influenzae* type b vaccines were licensed and incorporated into the routine immunization schedule of young children, epiglottitis has become rare in the United States. The differentiating features of epiglottitis are the fast and unrelenting course, accompanied by drooling and anxiety; and often the child is sitting and leaning forward. In most instances, the coryza, barking cough, and laryngitis characteristic of viral croup are not present with epiglottitis. Instead, the child's voice may be muffled.

Bacterial tracheitis is the second emergent entity that must be differentiated from viral croup. Bacterial tracheitis is a relatively uncommon infection that may affect children of any age and sometimes occurs after an episode of viral croup. The onset is acute with respiratory stridor, high fever, and copious, purulent secretions. As with epiglottitis, the child seems toxic, and the respiratory obstruction rapidly progresses, often necessitating tracheal intubation. The pathogens most often involved are *Staphylococcus aureus* and group A  $\beta$ -hemolytic streptococci. The diagnosis may be confirmed by direct laryngoscopy, which shows the purulent secretions and inflammation in the subglottic area, and sometimes by a lateral neck radiograph, which may reveal an area of subglottic narrowing with a shaggy membrane.

Infection of the deep neck spaces, including peritonsillar and retropharyngeal abscesses, may occasionally

### BOX 352-1 Differential Diagnosis of Acute Viral Laryngotracheobronchitis

#### INFECTIOUS CAUSES OF STRIDOR

- Epiglottitis
- Bacterial tracheitis
- Human papillomavirus (acquired perinatally)
- Retropharyngeal and parapharyngeal abscess

#### NONINFECTIOUS CAUSES OF STRIDOR

- Foreign body aspiration
- Vocal cord paralysis
- Angioneurotic edema of upper airway
- Hypocalcemic tetany
- Congenital malformations of upper airway
- Laryngotracheal malacia, web, cleft
- Vascular ring
- Tracheal stenosis
- Hemangioma, cyst of larynx or trachea
- Cystic hygroma
- Trauma

have features similar to those of viral croup and especially should be considered in a child with a history of a penetrating pharyngeal injury, such as that caused by a fish bone. Peritonsillar and retropharyngeal abscesses are commonly preceded by a mild pharyngitis and are more gradual in onset than croup. The child may be febrile with complaints of a sore throat and have difficulty in swallowing. Stridor usually is not present until the disease has markedly progressed. Important differential findings include a muffled voice, rather than a hoarse voice, the head held in a position allowing extension of the neck, the child resisting oropharyngeal examination, and progressive drooling and visible asymmetry to the wall of the posterior oropharynx. Diphtheria, which immunization fortunately has made rare, may be excluded by a history of adequate immunizations and by the absence of the characteristic gray pharyngeal or laryngeal diphtheritic membrane.

Multiple noninfectious entities can cause stridor, most of which (eg, congenital malformations, trauma) can be differentiated by obtaining a thorough history. An aspirated foreign body, among the more common causes of stridor, is abrupt in onset with respiratory distress; the lack of preceding respiratory symptoms, fever, and a history of previous choking on food or foreign body suggest this diagnosis. Acute edema of the upper respiratory tract caused by an allergic reaction may cause abrupt swelling and severe respiratory distress with stridor. The history of the circumstances of the abrupt onset, the lack of previous respiratory signs, and the concurrent onset of other manifestations of an allergic reaction, such as swollen lips and tongue and urticaria, are helpful in the differentiation from viral croup. (See Box 352-1.)

## EVALUATION

### History

The history is integral both in making the diagnosis of viral croup, as noted previously, and in assessing the severity of the illness on which the management depends. The child's prodromal signs, the characteristics of the onset of the illness, and the course of the development of the respiratory signs should be carefully obtained. A child with an atypical onset, with a rapidly progressive illness, with a history of recurrent episodes of illness with respiratory distress, or with an underlying condition may be at an increased risk for developing severe disease.

The typical history of a child with viral croup includes the child having had signs of an upper respiratory tract infection for 1 to 2 days. However, some children with few prior respiratory signs will awaken at night with the acute onset of spasms of cough, respiratory distress, and inspiratory stridor. This period is then followed by a characteristic cough, which may be spasmodic, with a deep brassy or harsh barking quality. This cough has been likened to a seal's bark and a brass bell. In 1836, Ley described the stridor as "the crowing of a cock, the yelping of a fox, the barking of a dog, the braying of an ass, or a ringing sound, as if the voice came from a brazen tube." Laryngitis with a raspy-sounding voice may also develop. Fever is commonly present, particularly with influenza and parainfluenza viral infections, and may reach 39.4°C to 40°C (103°F–104°F).

### Manifestations and Course of Croup

The pathophysiology of the development of croup in a young child explains the clinical manifestations, the course of illness, and potential complications (Figure 352-1). The virus initially infects the upper respiratory tract and produces congestion of the nasal passages and nasopharynx. The larynx, trachea, and often the bronchi, especially during primary infection, subsequently become involved. The 3 hallmark signs of croup—hoarseness, cough, and stridor, are produced primarily from the inflammation and obstruction of the larynx and trachea (Figure 352-1).

The stridor results from obstruction to airflow during both inspiration and expiration, but is most marked during inspiration. Because the subglottic region is outside the pleural cavity, the negative pressures generated on inspiration tend to narrow the passage further, similar to sucking on a partially occluded straw. Even minimal inflammation of the membranes lining the narrow passages of the larynx and glottis causes a considerable degree of obstruction, because resistance to airflow is inversely related to the fourth power of the radius of the airway. With subglottic obstruction, the child's tidal volume may decline, but may be compensated for by an increased respiratory rate. However, if the obstruction worsens and the child tires from the increased work of breathing, hypercarbia, hypoxemia, and respiratory failure can ensue (Figure 352-1).

### Physical Examination

On physical examination, therefore, the child's distress is most evident during inspiration. Each inspiratory

effort is marked audibly by the stridulous sound and is accentuated visibly by the retractions of the accessory muscles of the chest wall. The suprasternal, supraclavicular, and particularly the substernal retractions are characteristic of the inspiratory obstruction. Furthermore, distress may be marked by asynchronous movements of the chest wall and abdomen.

The respiratory rate is increased, but usually is not more than 50 breaths/min. This is in contrast to bronchiolitis, in which the picture of respiratory distress may be accompanied by respirations of 80 to 90 breaths/min. Auscultation of the chest reveals a prolonged inspiration, which may be accompanied by coarse crackles. Wheezes and rhonchi may also be heard on expiration. With more severe obstruction, the breath sounds may be diminished.

### Course of Illness

A varying intensity of the respiratory distress is characteristic of croup. The child may seem severely compromised and an hour later seem improved, only to worsen over the next hour. In some children, the symptoms seem to abate on waking in the morning but may worsen again as the day progresses. The signs of croup may extend over 3 to 4 or more days when untreated, but with dexamethasone therapy the respiratory stridor and distress usually are diminished within hours. The other signs associated with viral infection, such as nasal congestion and cough, may last longer.

In a few children, the respiratory distress may be unremitting or recurrent and associated with significant pneumonitis and hypoxemia leading to rapid, but shallow respirations, which indicate the child is fatiguing (Figure 352-1).

### Laboratory Testing

Croup is usually diagnosed based on the characteristic clinical findings and a compatible history. Laboratory testing is usually not necessary for most outpatients and may upset the child, causing an increased respiratory effort, which will augment the subglottic narrowing and obstruction to airflow. Laboratory evaluation should be limited to those tests necessary for management of a more severely ill child, such as tests needed for assessment of dehydration and oxygenation. The white blood cell count and differential usually are not helpful. The total white blood cell count may be normal or low from the viral infection. However, a mild shift to the left with an increased number of neutrophils and band forms may also occur in more distressed and hypoxemic children.

Multiple laboratory assays are available to determine the specific viral agent, including viral isolation, rapid antigen detection techniques such as immunofluorescence assays and enzyme immunoassays, and methods to detect viral RNA, as by RT-PCR. In most cases, however, specific diagnosis of the viral agent is not necessary and is not available in the time required for initial management decisions. In some instances, determination of the specific viral cause may be helpful in determining infection control procedures or when antiviral therapy, such as for influenza or RSV, is being considered.

**Figure 352-2** Radiograph of the posteroanterior neck of a child with viral croup, showing narrowing in the subglottic area.

### Imaging

Imaging is not usually necessary in diagnosing or managing children with viral croup. In some cases that are atypical or apt to be confused with other syndromes characterized by stridor, the differential diagnosis of croup may be aided by a lateral inspiratory and expiratory radiograph or by a posteroanterior radiograph of the neck (Figure 352-2). The air shadow of the larynx is seen to narrow, resembling an hourglass or a steeple, in the subglottic region as a result of the characteristic inflammation in this area. An inspiratory lateral view may also show distension of the hypopharynx. However, the variable sensitivity and specificity of neck radiographs for diagnosing viral croup make their value questionable.

## MANAGEMENT

The first phase of management is to evaluate which children may be cared for at home and which require hospitalization. Severity is often difficult to determine in this fluctuating disease, and no clinical signs are consistently prognostic of a complicated course. Clinical scoring systems, such as the Westley croup score, have been used to aid in the decision as to which children should be hospitalized. Toxic appearance, dehydration, and fatigue are indications for hospitalization. These are primarily based on such clinical findings as the degree of stridor, chest wall retractions, cyanosis, and the level of consciousness or fatigue (Table 352-2).

### Supportive Care

Supportive care is of prime importance for children with croup, whether they are outpatients or hospitalized. The child should be made comfortable to

avoid unnecessary anxiety and fatigue. Crying and anxiety tend to make the young child take rapid, short breaths, which aggravate the narrowing of the airway and the metabolic need for gas exchange. Fluids should be encouraged, and antipyretics may be given for fever and to diminish the associated increased respiratory rate and fluid requirements. Despite a multitude of cures passed down from generation to generation, few other home therapies have proved beneficial. Because of croup's fluctuating nature, several unverified therapeutic modalities may seem to work.

### Humidified Air

Humidified air from vaporizers, home-devised mist tents, and teakettles to showers have commonly been tried. The water particles that these devices produce, nevertheless, are generally too large to reach the lower respiratory tract, and are primarily helpful in humidifying the anterior nares and oropharynx. Furthermore, devices that use hot water and steam pose the potential hazard of accidental burns. Studies in children evaluating the efficacy of humidified air in treating croup are few and involve small numbers of patients, and no beneficial effects of mist have been proven.

### Nebulized Epinephrine

For children with severe croup, nebulized epinephrine, racemic or L-epinephrine, may be added to dexamethasone (Table 352-2). Epinephrine causes diminished subglottic swelling via its stimulus of  $\alpha$ - and  $\beta$ -adrenergic receptors, decreasing blood flow and swelling in the upper respiratory tract. The arterial oxygen saturation is not affected by the administration of epinephrine, and the amelioration of the clinical signs is transient. Thus, the child should be observed for at least 2 hours.

### Corticosteroid Therapy

Beyond supportive care, the major advance and mainstay in the management of both ambulatory and hospitalized children with viral croup is the use of dexamethasone (Table 352-2). Multiple well-designed trials have shown that 1 dose of dexamethasone orally or intramuscularly when necessary has resulted in significant clinical improvement within 24 hours, decreased hospitalization, fewer follow-up visits, and less need for additional medications. Although, in mild croup, many physicians prescribe dexamethasone for such children, the primary benefit supported by the evidence for mild croup is a modest 1-day reduction in the duration of illness. Some physicians and parents may not think that the potential risks of systemic steroids, even a single dose, are worth this magnitude of benefit.

### Antibiotic Therapy

Because croup is of viral etiology, antibiotics are rarely indicated. Secondary or concurrent bacterial infection is unusual, and antibiotics should be reserved for such documented cases.

**Table 352-2** Evaluation and Management of Children With Croup

	CROUP SEVERITY (WESTLEY SCORE)		
	MILD ( $\leq 2$ )	MODERATE (3–7)	SEVERE ( $\geq 8$ )
	Barking cough, hoarseness. No stridor, no or minimal chest wall retractions <i>at rest</i> , but may have them with crying or increased activity	Stridor and chest wall retractions <i>at rest</i> . No agitation	Stridor, sternal retractions <i>at rest</i> , accompanied by agitation or fatigue
<b>THERAPY</b>			
Decongestants, cough suppressants, antibiotics	Not recommended	Not recommended	Not recommended
Humidification	Not proven beneficial	Not effective	Not effective
Corticosteroids	Consider Dexamethasone (0.6 mg/kg, 1 dose PO)	Dexamethasone (0.6 mg/kg, 1 dose PO or IM)	Dexamethasone (0.6 mg/kg, 1 dose PO or IM)
Nebulized epinephrine	Not recommended	Consider nebulized racemic epinephrine (2.25%, 0.5 mL in 2.5 mL saline or L-epinephrine (1:1,000 dilution in 5 mL of saline)	Nebulized racemic epinephrine (2.25%, 0.5 mL in 2.5 mL of saline or L-epinephrine (1:1,000 dilution in 5 mL of saline)
<b>DISPOSITION</b>	Discharge home	Discharge to home if no stridor, no retractions at rest. If no improvement in 4 hours, consider hospitalization.	Observe for 2 hours. Good response: no recurrence, no stridor, no retractions at rest—discharge to home possible. Poor response: stridor, retractions at rest after 2 epinephrine doses—hospitalize

IM, intramuscular; PO, by mouth.

### WHEN TO REFER

- Child has a wheezing condition predisposing to more severe croup
- Child has a history of recurrent episodes of croup
- Episode of croup occurs during the neonatal period
- Symptoms progress despite supportive care at home

### WHEN TO ADMIT

- Child seems toxic, lethargic, in respiratory distress, or dehydrated
- Onset of illness was sudden with rapid progression of symptoms
- Signs of respiratory distress are unresponsive to outpatient drug therapy

## Chapter 353 DEHYDRATION

Prashant Mahajan, MD, MPH, MBA

The terms *volume depletion* or *hypovolemia* (a condition in which extracellular fluid is lost) and *dehydration* (a condition in which pure water loss occurs) are used interchangeably. The most common cause of dehydration is diarrheal illness, which results in 2.5 million deaths annually worldwide. Gastroenteritis causes more than 200,000 hospital admissions and more than 1.5 million outpatient visits every year in the United States. Although not a leading cause of death in the United States, gastroenteritis and related disorders result in a substantial amount of morbidity and generate significant health care costs.

### ETIOLOGY

Dehydration in infants and children is overwhelmingly the result of infectious processes. Of these processes, viral agents are of primary importance in the industrialized countries. Rotavirus and the Norwalk agent account for most cases of viral gastroenteritis in children. Some other causes of gastroenteritis are listed in Table 353-1.

Noninfectious causes of dehydration in children include agents that produce osmotic diarrhea, such as laxatives or cathartics that contain high concentrations of sugars; obstructive processes in the gastrointestinal tract; and, occasionally, vomiting as a sign of elevated intracranial pressure. Although each of these conditions occurs only rarely, they should be borne in mind when evaluating the child who is dehydrated and has a history that is not typical for infectious gastroenteritis. Finally, nondiarrheal causes of water and electrolyte loss can also result in severe dehydration. Losses can occur through the skin, respiratory system (ie, increase in insensible losses), or renal conditions. Losses that occur through the skin because of fever are usually in the range of a 10% to 15% rise in insensible losses for each 1°C rise in temperature above 38°C. A few

**Table 353-1**

### Causes of Pediatric Gastroenteritis

TYPE OF ORGANISM	COMMON	UNCOMMON
Viral	Rotavirus Norwalk Enteric adenovirus	Calicivirus Astrovirus
Bacterial	<i>Salmonella</i> <i>Shigella</i> <i>Campylobacter jejuni</i>	<i>Yersinia enterocolitica</i> <i>Vibrio cholerae</i> <i>Escherichia coli</i> <i>Clostridium difficile</i>
Parasitic	<i>Giardia lamblia</i>	<i>Entamoeba histolytica</i> <i>Cryptosporidium</i>

### BOX 353-1 Nondiarrheal Causes of Dehydration

#### WATER DEFICIT

- Nephrogenic diabetes insipidus
- Central diabetes insipidus

#### INCREASED INSENSIBLE LOSSES

- Premature infants
- Radiant warmers
- Phototherapy

#### INADEQUATE INTAKE OF WATER

- Ineffective breastfeeding
- Child abuse

#### WATER AND SODIUM DEFICITS

- Burns
- Excessive sweating
- Renal losses
- Diuretic use or abuse
- Diabetes mellitus
- Chronic renal disease, obstructive uropathy
- Cystic fibrosis, cystinosis, and other causes of the renal Fanconi syndrome

#### MISCELLANEOUS

- Surgical drains and third spacing

common causes of nondiarrheal dehydration are listed in Box 353-1.

### PATHOPHYSIOLOGIC MECHANISM OF DEHYDRATION IN GASTROENTERITIS

Children are at an increased risk for hypovolemia and dehydration because of the following:

1. Gastroenteritis is more common in children than in adults.

2. Very young children have higher surface-area-to-volume ratios than adults; thus, they have a proportionally higher rate of insensible losses, which can be accentuated in disease states.
3. Infants are less able to concentrate urine than are older toddlers and children.
4. Young children are often unable to communicate or actively seek fluids to replenish their losses.

To make the best-informed decisions about appropriate treatment of dehydration, primary care physicians should understand the basic principles underlying dehydrating diarrhea and the mechanisms by which rehydration occurs.

Regardless of which pathogen is involved, diarrhea and fluid loss ultimately result when intestinal fluid secretion exceeds the rate of absorption. In the case of viral agents and cytopathic bacteria, such as *Shigella*, *Salmonella*, *Campylobacter*, and enteropathogenic strains of *Escherichia coli*, fluid absorption is diminished because absorptive cells at the intestinal villus tip are destroyed. However, secretory processes that occur at the level of intestinal crypt cells remain unimpaired. On the other hand, toxin-producing bacterial pathogens such as *Vibrio cholerae*, toxigenic *E coli*, and some strains of *Shigella* cause significant increases in fluid secretion from crypt cells by deranging modulation of ion channels in the crypt cell membranes. Intestinal absorptive function is normal in such cases but does not keep pace with secretion, and diarrhea results.

Substantial fluid loss from the intestines or other sites depletes intravascular volume, resulting in end-organ hypoperfusion and poor nutrient and oxygen delivery; ultimately, tissue acidosis develops. Elevated aldosterone levels resulting from hypovolemia lead to renal potassium loss. Eventually, circulatory collapse and shock occur; irreversible organ damage and death may follow. The chain of events can be interrupted by very rapid repletion of fluids to restore circulating volume, reverse acidosis, and improve perfusion and end-organ function.

## EVALUATION

All children with dehydration should be systematically evaluated with the following 5-point assessment:

1. What is the magnitude of volume deficit?
2. Is osmolar imbalance present?
3. Is acid-base disturbance present?
4. Is abnormality in potassium metabolism present?
5. Is the renal function impaired?

The 5-point assessment can be evaluated by a combination of clinical and laboratory techniques as detailed in Table 353-2.

### Physical Examination

During the initial evaluation of a child with dehydration, physicians must determine and document the degree of dehydration. Volume depletion is most objectively measured as a change in weight from baseline. Ideally, the pre-illness weight should be used to determine the exact proportion of weight loss that is attributable to the fluid deficit. Given that the pre-illness weight is often unavailable, physicians should use pulse rate, blood pressure, urine output, skin turgor, and other signs (Table 353-3) to categorize the

**Table 353-2**

### Five-Point Assessment of Dehydration

POINT OF ASSESSMENT	METHOD
Volume deficit	History and physical examination
Osmolar disturbance	Serum sodium and serum osmolality measurement
Acid-base disturbance	Blood pH, PCO <sub>2</sub> , and serum bicarbonate measurement
Potassium	Serum potassium
Renal function	Blood urea nitrogen, creatinine, urine specific gravity

PCO<sub>2</sub>, partial pressure of carbon dioxide.

child as having mild (3%–5% volume loss), moderate (6%–9% volume loss), or severe dehydration (≥10% volume loss).

### Laboratory Evaluation

Laboratory testing is used to determine the clinical condition of the child and the origin of dehydration. Many children with mild or moderate dehydration do not need any laboratory tests. The minimal amount of testing in patients with moderate to severe dehydration is measurement of serum electrolytes, including sodium, potassium, chlorides, and bicarbonates, along with blood urea nitrogen, serum creatinine, urine specific gravity, and serum glucose (by the finger-prick method at the bedside). Laboratory testing is less useful in assessing the degree of volume depletion. A review of the literature and a prospective study found that only serum bicarbonate (<17 mEq/L) differentiated a child with moderate or severe hypovolemia from one with mild hypovolemia. Serum sodium measurements are useful in categorizing the child as having isotonic or hyponatremic (150 mEq/L) dehydration. The signs of dehydration (see Table 353-3) will be delayed if the patient has hypernatremic dehydration (ie, higher relative loss of free water as compared with loss of sodium), because the increased serum sodium causes an osmotically driven fluid shift from the intracellular compartment to the extracellular compartment. Similarly, the signs of dehydration are present earlier if the child has hyponatremic dehydration. Serum potassium levels may be falsely elevated (acidosis causes a shift from the intracellular compartment) or low (caused by losses in the gastrointestinal tract). Urine osmolality and specific gravity will be high (often exceeding 450 mOsm/kg), but may be low if the patient has lost renal concentrating ability (in patients with osmotic diuresis or diabetes insipidus). Stool diagnostic studies similarly should be used sparingly. Bacterial cultures certainly should be obtained in ill-seeming children, those with fever (≥38°C in infants younger than 3 months and ≥39°C in children older than 3 months), those who have bloody or mucoid stools, or those in whom a travel or

**Table 353-3** Degree of Dehydration

PARAMETER	DEGREE OF DEHYDRATION		
	MILD	MODERATE	SEVERE
Weight loss (%)—infants	5	10	15
Weight loss (%)—children	3	6	>9
Skin color	Pale	Gray	Mottled
Skin turgor	May be normal	Decreased	Tenting
Mucous membranes	Slightly dry	Dry	Dry, parched, collapse of sublingual veins
Eyes	Normal	Decreased tears	Sunken, absence of tears
Central nervous system	Alert but thirsty	Irritable	Lethargic, grunting, coma
Pulse	Normal and strong	Rapid and slightly weak	Significantly tachycardic and very weak to not palpable
Capillary refill	Normal (<2 sec)	2–4 sec	>4 sec
Blood pressure	No change	Orthostatic decrease	Shock
Urine	Normal to mildly reduced	Significantly reduced	Anuria
Volume of deficit—infants	50 mL/kg	60 mL/kg	150 mL/kg
Volume of deficit—children	30 mL/kg	100 mL/kg	>90 mL/kg

exposure history is suggestive of enteric pathogens. Most children will not meet these criteria, and routine stool cultures should be discouraged. Similarly, little additional diagnostic or therapeutic guidance is provided by detection of the rotavirus antigen in stool samples, and such studies rarely should be performed.

## TREATMENT

### Principles of Fluid Therapy

In children, dividing fluid therapy into replacement therapy (corrects deficit) and maintenance therapy (replaces ongoing losses, including insensible losses) is useful. Details of maintenance therapy are provided in Chapter 58, Fluids, Electrolytes, and Acid-Base Composition. Replacement therapy is based on 2 steps.

1. First-fluid (emergent) phase: This phase restores moderately or severely compromised effective circulating volume and prevents tissue damage. This phase is typically begun with a 20-mL/kg fluid bolus with isotonic saline (0.9 normal saline [NS]) or lactated Ringer solution over 1 to 2 hours. Fluid boluses should be repeated until signs of shock begin to disappear. Although some advantages can be found for using colloid solutions (albumin or hetastarch, namely that the colloid solutions remain for a longer time in the intravascular space and have a lower risk of developing pulmonary edema caused by dilutional hypoalbuminemia), many clinical trials have failed to demonstrate these theoretical benefits.
2. Second-fluid phase: This phase essentially replaces the body's fluid and electrolyte loss and can be in the form of parenteral intravenous fluids or oral replacement as oral rehydration therapy (ORT).

Physicians should recognize that, in mild to moderate cases of dehydration, this phase will often suffice and the physician may not have to resort to the first-fluid or emergent phase. Administration of ORT is discussed later in this chapter. Intravenous fluids are often indicated if the child is unable to undergo ORT because of altered mental status or persistent vomiting, or has severe electrolyte abnormalities. The type of intravenous fluids used depends on the serum sodium levels (ie, whether the child has isonatremia, hyponatremia, or hypernatremia). Most cases of dehydration in children are associated with isonatremia and can be managed over a few hours in an ambulatory setting (either the physician's office or the observation unit in an emergency department). Table 353-4 provides details about the estimated water and electrolyte deficits associated with moderate-to-severe dehydration.

### Controversies Regarding Optimal Fluid Management in Dehydration

Although rapid reexpansion of the extracellular fluid volume with 0.9% saline followed by ORT has become the gold standard therapy in infants with moderate-to-severe dehydration, few physicians are actually using this therapeutic regimen. Tables 353-5, 353-6, and 353-7 provide examples of a child who is 10% dehydrated with isonatremic, hyponatremic, and hypernatremic dehydration.

Normal saline or 0.9 NS solution has 154 mEq/L of sodium, and half normal saline or 0.45 NS has 77 mEq/L of sodium. Similarly, 0.25 NS has 38 mEq/L of sodium. Physicians should be aware of these sodium concentrations in intravenous fluids while calculating replacement of maintenance and ongoing losses

**Table 353-4** Estimated Fluid and Electrolyte Deficits in Moderate-to-Severe Dehydration

TYPE OF DEHYDRATION	WATER (mL/Kg)	SODIUM (mEq/kg)	POTASSIUM (mEq/kg)	CHLORIDE AND BICARBONATE (mEq/kg)
Isonatremic	100–150	8–10	8–10	16–20
Hyponatremic	50–100	10–14	10–14	20–28
Hypernatremic	120–180	2–5	2–5	4–10

**Table 353-5** Intravenous Fluids for a 5-kg Child With 10% Dehydration and Normal Serum Sodium

	WATER	SODIUM	POTASSIUM
Maintenance <sup>a</sup> Deficit <sup>b</sup>	5 kg × 100 mL/kg per day = 500 mL Weight × % dehydration	3 mEq/100 mL = 15 mEq Sodium in ECF × proportion of fluid loss from ECF × deficit (mL)	2 mEq/100 mL = 10 mEq Potassium in ICF × propor- tion of fluid loss from ECF × deficit (mL)
	5 kg × 0.1 = 0.5 g (500 mL)	135 mEq/L × 0.6 × 500 mL = 40 mEq	150 mEq/L × 0.4 × 500 mL = 30 mEq
Ongoing losses	Replace mL-for-mL	Add sodium in proportion to expected fluid loss (stool, gastric contents, etc)	Add potassium in proportion to expected fluid loss (stool, gastric contents, etc)
Total	1,000 mL	55 mEq	40 mEq

ECF, extracellular fluid; ICF, intracellular fluid.

<sup>a</sup>After the initial bolus, maintenance fluids are administered over 24 hours; one-half the deficit is given over 8 hours and the remainder over 24 hours.<sup>b</sup>The water and sodium content in the initial bolus of normal saline does not count toward either maintenance or replacement of ongoing losses or deficit therapy.**Table 353-6** Intravenous Fluids for a 5-kg Child With 10% Dehydration and Hyponatremia (Serum Sodium = 128 mEq/L)

	WATER	SODIUM	POTASSIUM
Maintenance <sup>a</sup> Deficit <sup>b</sup>	5 kg × 100 cc/kg/d = 500 mL Weight × % dehydration	3 mEq/100 mL = 15 mEq Sodium in ECF × proportion of fluid loss from ECF × deficit (mL) PLUS (desired sodium – observed sodium) × weight × sodium in ECF	2 mEq/100 mL = 10 mEq Potassium in ICF × propor- tion of fluid loss from ECF × deficit (mL)
	5 kg × 0.1 = 0.5 g (500 mL)	135 mEq/L × 0.6 × 500 mL = 40 mEq PLUS (135 mEq/L – 128 mEq/L) × 5 × 0.6 = 21 mEq	150 mEq/L × 0.4 × 500 mL = 30 mEq
Ongoing losses	Replace mL-for-mL	Add sodium in proportion to expected fluid loss (stool, gastric contents, etc)	Add potassium in proportion to expected fluid loss (stool, gastric contents, etc)
Total	1,000 mL	76 mEq	40 mEq

ECF, extracellular fluid; ICF, intracellular fluid.

<sup>a</sup>After the initial bolus, maintenance fluids are administered over 24 hours; one-half the deficit is given over 8 hours and the remainder over 24 hours.<sup>b</sup>The water and sodium content in the initial bolus of normal saline does not count toward either maintenance or replacement of ongoing losses or deficit therapy.

**Table 353-7** Intravenous Fluids for a 5-kg Child With 10% Dehydration and Hypernatremic Dehydration (Serum Sodium = 160 mEq/L)

	WATER	SODIUM	POTASSIUM
Maintenance	5 kg × 100 mL/kg/d = 500 mL	3 mEq/100 mL = 15 mEq	2 mEq/100 mL = 10 mEq
Deficit	Weight × % dehydration  5 kg × 0.1 = 0.5 g (500 mL)	Free water deficit = ([observed sodium – desired sodium] weight × 4 mL/kg); thus, free water deficit = (160 – 145) × 5 kg × 4 mL/kg = 300 mL Sodium in ECF × proportion of fluid loss from ECF × (total deficit – free water deficit) 135 mEq/1,000 mL × 0.6 × (500 – 300 mL) = 16 mEq/L	Potassium in ICF × propor- tion of fluid loss from ECF × deficit (mL); thus, free water deficit = (160 – 145) × 5 kg × 4 mL/kg = 300 mL 150 mEq/L × 0.4 × (500 – 300 mL) = 12 mEq
Ongoing losses	Replace mL-for-mL	Add sodium in proportion to expected fluid loss (stool, gastric contents, etc)	Add potassium in proportion to expected fluid loss (stool, gastric contents, etc)
Total	1,000 mL	31 mEq	22 mEq

ECF, extracellular fluid; ICF, intracellular fluid.

of fluids and electrolytes. In general, in the presence of otherwise normally functioning kidneys, most patients will do well with 0.45 NS or 0.9 NS when it is used as replacement solution.

### Oral Rehydration

Fluid absorption can be promoted by the enteral administration of properly designed fluids, even in the face of ongoing losses. In healthy adults, more than 6,500 mL per day of fluids, including both ingested liquids and intestinal secretions, are introduced into the intestinal tract and reduced to form a stool output of less than 100 mL per day. Oral rehydration exploits a normal cellular process known as cotransport, in which absorption of a molecule of an organic substrate promotes the absorption of an ion of sodium from the small intestine. With enhanced absorption of sodium, water, in turn, is absorbed rapidly into the circulation. Intravascular fluid volume can be restored in this fashion rapidly and reliably.

A fluid that is designed to promote water and electrolyte absorption through the cotransport system in the gut is referred to as an *oral rehydration solution* (ORS). A physiologically appropriate ORS contains 70 to 90 mEq/L sodium and not more than 25 g/L of glucose. In addition, an ORS typically contains 20 mEq/L of potassium and 30 mEq/L of base in the form of citrate. Almost all juices, soft drinks, and punches contain much higher concentrations of sugars and almost no sodium, making them inappropriate for use as ORSs. In fact, the higher sugar concentrations in these fluids may exacerbate diarrhea by presenting a large osmotic load within the intestinal lumen.

An ORS can be used to restore both fluid and electrolyte balance in children who have a wide range of initial serum sodium values. By the end of the rehydration

period, both hypernatremia and hyponatremia generally have resolved.

## MANAGEMENT

Most dehydrated children can be rehydrated successfully without resorting to parenteral (intravenous or intraosseous) therapy. The combined use of an ORS and an appropriate regimen of refeeding is referred to as *oral rehydration therapy* (ORT). The number of deaths worldwide that are attributable to diarrhea in children younger than 5 years fell from 4.6 million to 1.5 million per year from 1980 to 2000 concomitant with the increased use of ORT. In addition, ORT has been found to have a low failure rate (4%) and to lead to reduced hospital stays and fewer adverse events, and was less expensive than intravenous therapy.

### Intravenous Rehydration

Patients who have severe dehydration (shock) should receive initial rehydration fluids parenterally via either the intravenous or, when line placement proves difficult, the intraosseous route. Patients treated parenterally should be given rapid boluses of 0.9% sodium chloride in initial volumes of 20 mL/kg for not more than 20 minutes. In especially severe cases, it is not unusual for patients to require 60 to 100 mL/kg before the restoration of circulating volume is apparent. Enteral fluid therapy may begin immediately by either the mouth or a nasogastric tube, provided that the patient is conscious and airway protective reflexes are intact. It is important to note that there may be an increased incidence of iatrogenic hyponatremia with the use of hypotonic solutions in the maintenance phase of intravenous hydration. This has led some experts to recommend using 0.9 NS as maintenance fluid after the initial bolus therapy.

**Table 353-8** Solutions Commonly Used in Children Who Have Diarrhea

SOLUTION	GLUCOSE/PHENOL (g/L)	SODIUM (mEq/L)	BASE (mEq/L; CITRATE OR BICARBONATE)	POTASSIUM (mEq/L)	OSMOLALITY (mmol/L)

UNICEF, United Nations International Children's Emergency Fund; WHO, World Health Organization.

<sup>a</sup>Rice syrup solids.

### Oral Rehydration

In the conscious child who has mild or moderate dehydration, fluid replacement always should be initiated orally. Successful ORT depends on proper fluid selection and skilled administration. Simply instructing parents to purchase and feed a child an ORS is unlikely to result in success and satisfaction.

### Types of Oral Rehydration Solutions

In the industrialized world, ORSs are most widely available commercially as premixed liquids. These solutions contain sodium levels varying from 50 to 70 mEq/L. For the mildly dehydrated child, any of these solutions is appropriate. For more significantly dehydrated infants and children, a solution containing 70 to 90 mEq/L of sodium should be chosen. Packets of oral rehydration salts for preparation of a solution containing 90 mEq/L of sodium are available for mixing with 1 L of water to provide an inexpensive and reliable alternative. These packets always should be distributed with a 1-L bottle to promote proper mixing. Juices, punches, and other soft drinks are inappropriate solutions for children who have diarrhea because of the high osmotic load they introduce into the intestines. Table 353-8 lists the most commonly available solutions and their compositions. Information on juices and soft drinks is provided for comparison. The World Health Organization (WHO) formula (2002) contains 13.5 g/L of carbohydrates, 75 mEq/L of sodium, 20 mEq/L of potassium, and 30 mEq/L of bicarbonate base, and has an osmolarity of 245 mOsm/kg of water. The desired properties for an ORS as recommended by WHO and the United Nations International Children's Emergency Fund (UNICEF) for global use include the following:

1. Total osmolality between 200 and 310 mmol/L
2. Equimolar concentrations of glucose and sodium
3. Glucose concentration not in excess of 20 g/L (111 mmol/L)
4. Sodium concentration between 60 and 90 mEq/L
5. Potassium concentration between 15 and 25 mEq/L

6. Citrate concentration between 8 and 12 mmol/L

7. Chloride concentration between 50 and 80 mEq/L

Although homemade sugar-salt solutions can be prepared to produce an appropriate ORS, the risk of incorrect mixing is high. Such homemade solutions should not be used when commercial solutions are available.

### Administration of Oral Replacement Therapy

In general, ORT can be started in the office or emergency department immediately after assessment excludes acute abdominal processes (eg, appendicitis, volvulus, intussusception, pyloric stenosis) and extraintestinal causes of fluid losses (eg, intracranial hypertension caused by tumor, meningitis, or hydrocephalus, all of which may induce volume loss as a result of vomiting). Ideally, the goal is to replace the entire fluid deficit in the first 4 to 6 hours (Table 353-9).

### Rehydration Phase

Fluids are best administered initially by a parent who is instructed to place the fluids into the child's mouth (via a needleless syringe), 1 teaspoon (5 mL) per minute for infants, 10 mL/min for toddlers, and 15 mL/min for older children. This amount, at a steady rate of administration, provides 300, 600, and 900 mL/h, respectively, which generally replaces the calculated deficit within a 4- to 6-hour period. Frequent reassessment of the child and encouragement of the parent are crucial during this rehydration period. The rehydration phase should be completed in the office, clinic, or emergency department before the child is sent home. In general, vomiting is not a contraindication to ORT. Even when vomiting occurs, steady fluid replacement is continued orally. Children usually do not discharge their entire stomach contents when they vomit. As dehydration and tissue acidosis are corrected, the frequency and severity of vomiting are generally reduced. However, children who only have vomiting (without diarrhea) warrant especially careful evaluation for conditions other than gastroenteritis, such as appendicitis, intussusception, volvulus, or pyloric stenosis, depending on age.

**Table 353-9** Fluid Therapy for Dehydration

DEGREE OF DEHYDRATION <sup>a</sup>	SIGNS	REHYDRATION PHASE (FIRST 4HR; REPEAT UNTIL NO SIGNS OF DEHYDRATION REMAIN)	MAINTENANCE PHASE <sup>c</sup> (UNTIL ILLNESS RESOLVES)
Mild (3%–5%)	Slightly dry mucous membranes, increased thirst	ORS 60 mL/kg <sup>b</sup>	Breastfeeding, undiluted lactose-free formula, half-strength cow milk, or lactose-containing formula
Moderate (6%–9%)	Sunken eyes, sunken fontanelle, loss of skin turgor, dry mucous membranes, decreased urine output	ORS 80 mL/kg	Same as above
Severe (>10%)	Signs of moderate dehydration plus 1 or more of the following: rapid thready pulse, hypotension, cyanosis, rapid breathing, delayed capillary refill, markedly reduced or absent urine output, lethargy, coma	Intravenous or intraosseous isotonic fluids (0.9% saline or lactated Ringer solution), 20 mL/kg over 1 h; repeat until pulse and state of consciousness return to normal, then 50–100 mL/kg of ORS based on remaining degree of dehydration <sup>d</sup>	Same as above

ORS, oral rehydration solution.

<sup>a</sup>Percent of total body weight lost.

<sup>b</sup>If no signs of dehydration are present, the rehydration phase may be omitted. Proceed with maintenance therapy and replacement of ongoing losses.

<sup>c</sup>While parenteral access is being sought, nasogastric infusion of ORS may be administered at 30 mL/kg/hr, provided airway protective reflexes remain intact.

<sup>d</sup>In addition to the rehydration amounts shown, replace ongoing stool losses and vomitus with ORS, 10 mL/kg for each diarrheal stool and 5 mL/kg for each episode of vomitus.

### Maintenance Phase

At the end of 4 hours, the state of hydration should be reassessed by using the original clinical criteria. If detectable dehydration remains, then the rehydration phase should be repeated based on the remaining calculated volume deficit. If rehydration has been completed, then the maintenance phase is begun. In this phase, the parent is instructed to continue to administer an ORS in ad libitum quantities, but to alternate this fluid intake with human milk, formula, or other appropriate feedings. Regular feedings should not be withheld once rehydration is complete. Strong evidence suggests that both the volume and the duration of diarrhea are reduced when children are fed immediately after rehydration.

### Children Treated in Emergency Departments

The subpopulation of children who seek treatment at emergency departments may represent a distinct group of patients. These children have often seen a primary care physician earlier in the illness, and the physicians may have attempted to rehydrate the children orally. Although use of ORT in the emergency department should be strongly encouraged and should always be attempted in the mildly and moderately dehydrated child, physicians should realize that ORT in these children will likely fail. Therefore, intravenous treatment probably will be required, especially in the older (school-age) child in whom vomiting is the most prominent feature. Such children are often simply too exhausted to continue with efforts to drink. A brief trial of ORT followed, if necessary, by a brief course of intravenous

fluids and subsequent reintroduction of liquids and solids is a reasonable approach in such children.

### Management of Children With Acute Renal Failure

For fluid management in children with acute renal failure, physicians need to obtain additional testing, such as serum blood urea nitrogen, serum creatinine, urinary electrolytes, and urinary creatinine to assess the status of kidney function and determine whether renal failure is largely caused by severe hypovolemia (prerenal azotemia) or secondary to renal damage. Apart from the aforementioned tests, the fractional excretion of sodium (FENa) is one way of differentiating prerenal disease (a reduction in glomerular filtration rate caused solely by decreased renal perfusion) from acute tubular necrosis (ATN), the 2 most common causes of acute kidney injury. FENa is calculated by dividing the product of urinary sodium and serum creatinine by the product of serum sodium and urinary creatinine, expressed as a fraction. In general, a FENa value below 1% indicates prerenal disease whereas a value above 2% usually indicates ATN. Although there are some exceptions to this rule, the FENa is generally more accurate than the urine sodium concentration in differentiating prerenal disease from ATN because it directly measures sodium handling.

Children with acute renal failure should be categorized as hypovolemic, euvolemic, or hypervolemic, and fluid replacement should be adjusted based on this

categorization. This should be in conjunction with ongoing assessment of serum electrolytes and measures of renal function (blood urea nitrogen and serum creatinine) and acid-base status. In general, vigorous fluid management is recommended in hypovolemic patients to prevent patients in prerenal azotemia from progressing to ATN, and should include normal saline bolus along with replacement of ongoing losses and provision of maintenance fluids. In euvoletic children, ongoing fluid losses (insensible fluid [300–500 mL/m<sup>2</sup> per day], urine, and gastrointestinal losses) need to be balanced with administered fluids. Patients who are hypervolemic (ie, have signs of fluid overload) will require either fluid removal with a trial dose of furosemide to convert the oliguric renal failure to nonoliguric state or fluid restriction. Furthermore, it is important to restrict or even avoid potassium- and phosphorous-containing fluids in anuric or oliguric patients. Sodium should be replaced at 2 to 3 mEq/kg per day to ameliorate fluid accumulation and hypertension.

## COMPLICATIONS

Complications of inadequately treated dehydration may be severe, ultimately including full-blown shock and multiorgan dysfunction syndrome, with end-organ damage to the kidneys, liver, and brain, culminating in death. In practice, such extreme consequences may be prevented readily by early and aggressive fluid therapy, using the oral or, occasionally, the intravenous or intraosseous routes. As a rule, risking overhydration is far better than being exceptionally cautious with fluid administration. On rare occasions, aggressive oral hydration has resulted in mild overhydration, with some transient periorbital puffiness and a 2% to 3% weight gain. These findings are generally self-limited and of no clinical consequence.

Hypokalemia, which results from the losses of total body potassium as a consequence of the increased aldosterone activity in the kidney, is a common occurrence in severe dehydration. As sodium is avidly retained, potassium is lost in the urine. Hypokalemia can result in ileus, which may impair fluid and electrolyte absorption from the intestines. An ORS generally contains 20 mEq/L potassium chloride; such a solution is capable of restoring potassium balance.

## PROGNOSIS

Although diarrheal dehydration is the leading cause of death among children globally, when appropriately treated, it carries an excellent prognosis. Rapid restoration of circulating volume coupled with proper dietary management results in maintenance of hydration and earlier resolution of diarrheal symptoms. Parents should be warned, however, that even with ideal therapy, typical episodes of gastroenteritis last 3 to 7 days. Parents and pediatricians should be reassured about the child's state of good hydration. The physician should reinforce the idea that the diarrheal illness itself is of little consequence as long as hydration is maintained and feeding reintroduced in a timely fashion.

## SUMMARY

Dehydration resulting from gastroenteritis is a common condition generally managed by ORT on an outpatient

basis. Little laboratory evaluation is necessary. Parenteral therapy is reserved for severe or unusual cases. Regardless of the route of delivery, fluid should be administered rapidly and with the intent to restore the entire fluid deficit in 4 to 6 hours. Proper dietary management is essential to minimize the severity and duration of symptoms.

## WHEN TO ADMIT

- The child has a persistently abnormal mental status, persistently abnormal electrolyte levels, or chronic diarrhea (>14 days' duration).
- The child has other medical problems, such as short gut syndrome and inflammatory bowel disease.
- The child's hydration status cannot be restored or maintained after a 6-hour outpatient treatment period.

## Chapter 354 DIABETIC KETOACIDOSIS

Alaa Al Nofal, MD; W. Frederick Schwenk II, MD;  
Peter Tebben, MD

Diabetic ketoacidosis (DKA) is the metabolic consequence of absolute insulin deficiency, or its ineffectiveness in the presence of counterregulatory hormones (cortisol, growth hormone, glucagon, etc) during stressful situations such as major illnesses or surgery. This condition represents a medical emergency that requires meticulous attention to optimize outcomes. The biochemical hallmarks of this disorder are hyperglycemia and acidosis. Historically, DKA has been associated with type 1 diabetes (T1D); however, clearly patients with type 2 diabetes (T2D) may develop DKA. Hispanic and African-American youth with T2D seem to be more prone to developing DKA than other populations. With the increasing incidence of both T1D and T2D, early recognition and appropriate intervention are imperative to prevent the significant morbidity and mortality associated with DKA.

DKA is often present at the time of initial diagnosis in patients with T1D. The risk of developing DKA at the onset of diabetes has been associated with factors such as younger age, lower socioeconomic status, and the absence of family history of a parent or a sibling with diabetes. Most children with newly diagnosed T1D who have DKA will have symptoms consistent with the diagnosis, including polyuria, fatigue, and weight loss.

Despite improvement in the understanding of diabetes and methods for its treatment, recurrent DKA remains a significant problem. Box 354-1 lists several factors associated with an increased risk of DKA in patients with established diabetes. Teens, patients with high HbA1c values, and patients with high reported daily insulin doses have been reported to have an increased incidence of DKA. A high risk of DKA

### BOX 354-1 Risk Factors for Diabetic Ketoacidosis in Patients With Established Type 1 Diabetes

- Poor glycemic control (higher HbA1c)
- Previous episode of DKA
- Coexisting psychiatric disorders
- Lower socioeconomic status (underinsured/lack of access to medical care)
- Adolescent age (especially girls 13–19 years of age)
- Patients with high reported insulin requirements

has also been reported in children who were underinsured or diagnosed as having a coexisting psychiatric disorder. The presence of previous episodes of DKA also confers a particularly high risk of recurrence. Several investigators have reported that only a few patients account for a significant proportion of DKA cases.

### DEFINITION

DKA results from a lack of insulin effect, which leads to decreased peripheral glucose utilization despite continued hepatic glucose production. Counterregulatory hormones including glucagon, catecholamines, and cortisol may have elevated levels and contribute to the hyperglycemia. Fat stores are broken down in the absence of adequate insulin action, which leads to ketone body formation and subsequent metabolic acidosis. Criteria for the biochemical diagnosis of DKA were proposed in a consensus statement from the European Society for Pediatric Endocrinology and the Pediatric Endocrine Society (ESPE/PES) and in the International Society of Pediatric and Adolescence Diabetes 2009 consensus guidelines. The biochemical requirements include a blood glucose level greater than 200 mg/dL and metabolic acidosis with a venous pH less than 7.3 or bicarbonate level less than 15 mmol/L. In the context of uncontrolled diabetes, an elevated serum  $\beta$ -hydroxybutyrate ( $>3.0$  mmol/L) is another helpful diagnostic tool. These findings are associated with ketonemia and ketonuria. Although these criteria identify most patients, a glucose concentration of less than 200 mg/dL does not always rule out the possibility of DKA, especially in young, partially treated children and children who are fasting or have consumed only a small amount of carbohydrates.

### DIFFERENTIAL DIAGNOSIS

In the early stages, signs and symptoms of DKA can be nonspecific and may be misdiagnosed as gastroenteritis or reactive airway disease exacerbation. When the biochemical criteria listed previously are applied to define DKA, the diagnosis is usually straightforward. During the initial assessment of a patient with DKA, the precipitating factors associated with the episode should be identified. Many factors have been described to precipitate an episode of DKA (Box 354-2). In young adults with diabetes, myocardial infarction

**BOX 354-2 Factors Associated With Diabetic Ketoacidosis in Children and Adolescents**

Omission of insulin  
Insulin pump failure or disconnection  
Illness  
Trauma  
Surgery  
Alcohol  
Medications  
Depression

and stroke should also be considered. The omission of insulin is the most common cause of DKA in children and young adults with established diabetes mellitus. Insulin doses are sometimes not given during illness, especially if the patient is not eating. Failure to recognize the ongoing need for insulin (and sometimes increased requirements) during illness is a common mistake that is best addressed by providing adequate education to the patient and family. In addition to missed or inadequate insulin dosing, illness and trauma may contribute to the occurrence of DKA. Continuous infusion pump failure or disconnection should be considered in every patient on a pump presenting with DKA. Primary care physicians should also consider the relative contribution of other illnesses to the metabolic acidosis. Lactic acidosis as a result of sepsis or poor perfusion may coexist with DKA, and its cause should be treated concurrently.

**EVALUATION****Relevant History**

Most patients with T2D have a family history of diabetes. In contrast, a relatively small percentage of patients with T1D have another family member with the disease. The symptoms a patient with DKA reports vary and are consistent with the degree of metabolic disturbance. As insulin deficiency progresses and blood glucose levels rise, the renal threshold for glucose reabsorption in the proximal tubule is surpassed ( $\approx 180$  mg/dL). An osmotic diuresis ensues, leading to symptoms of polyuria and polydipsia. With excess renal water loss, obligate losses of sodium, potassium, and phosphorus also occur. The osmotic diuresis can lead to enuresis in previously continent children. Weight loss caused by dehydration and the loss of calories in the urine is often reported but difficult to quantify unless a recent accurate weight is available. If the child has limited access to fluids or is vomiting, dehydration can be severe. Fatigue is a common symptom that may be evident even before significant dehydration and acidosis. Polyphagia may be evident early in the disease but is typically replaced with a loss of appetite as ketosis and metabolic acidosis worsen. Patients who develop moderate to severe ketoacidosis often experience abdominal pain and vomiting, which contribute to the dehydration, thereby reducing the

glomerular filtration rate and thus impairing the clearance of glucose and ketones. The state of metabolic acidosis results in alveolar hyperventilation (Kussmaul breathing pattern). Families may notice a fruit odor of acetone on the patient's breath.

The early recognition of DKA in infants and young children can be particularly challenging. Infants and young children are not able to verbalize their symptoms. In addition, an infant's inability to access fluids freely may mask the polyuria. Increased urine production may also be difficult to judge based on how wet infants' diapers are or how frequently the diapers need to be changed. Parents are less likely to recognize symptoms of hyperglycemia and DKA in children younger than 2 years. This circumstance may lead to a delay in the diagnosis of diabetes and partially explain why more children in this age group experience DKA at the time of the initial diagnosis compared with older children.

**Physical Examination**

Similar to historical clues that should prompt consideration of the diagnosis of DKA, physical findings are commensurate with the degree of metabolic disturbance. Despite many patients having moderate to severe dehydration at the time of diagnosis, few become hypotensive. If a patient is in shock, a coexisting illness should be considered.

**Dehydration**

True dehydration (intracellular and extracellular fluid loss) rather than simple hypovolemia (intravascular fluid loss) is the rule. As the intravascular osmolality increases as a result of hyperglycemia, water shifts from the intracellular space into the vascular space. This process results in an osmotic diuresis, leading to profound water and electrolyte loss if the cycle remains uninterrupted. Clinically assessing the degree of dehydration is an important part of assessing a child with DKA because over- or underestimating the degree of dehydration may affect the child's outcomes. Assessing the degree of dehydration can be difficult because of the extravascular and intravascular components of dehydration in DKA, but weight loss, tachycardia, delayed capillary refill time, and reduced skin turgor may be useful signs. Most children with moderate to severe DKA are considered to be 5% to 10% dehydrated.

**Acid Load**

As expected in a child with metabolic acidosis, compensatory respiratory mechanisms attempt to correct the excess acid load. This correction is accomplished by increasing the minute ventilation, which may be evident as rapid, deep respirations (Kussmaul breathing).  $\beta$ -hydroxybutyrate, acetoacetic acid, and acetone are produced in excess in children with DKA. Although acetone does not contribute to the acid load, as it is exhaled, a fruity breath odor may be detected.

**Neurologic Signs**

When DKA goes untreated and becomes severe, neurologic signs may become prominent. Confusion and an altered sensorium may be observed. Seizures and

**Table 354-1**  
**Estimate of Fluid and Electrolyte Deficits in Children With Diabetic Ketoacidosis**

FLUID OR ELECTROLYTE	EXTENT OF LOSS PER KG BODY WEIGHT
Water	60–100 mL/kg
Sodium	6 mEq/kg (range 5–13)
Potassium	5 mEq/kg (range 4–6)
Chloride	4 mEq/kg (range 3–9)
Phosphate	3 mEq/kg (range 2–5)

Modified from Schwenk WF 2nd, Haymond MW. Treatment of diabetic ketoacidosis in children and young adults. *Prim Care*. 1983;10(4):663–676. Copyright © 1983, Elsevier, with permission.

coma may also occur as a complication of DKA. Although cerebral edema typically has been reported after the initiation of therapy, cases have been described where edema has been present before therapeutic intervention. Cerebral edema should be considered in all children with DKA who exhibit signs or symptoms of neurologic compromise regardless of whether treatment has been initiated.

### Laboratory Findings

As previously mentioned, hyperglycemia (glucose >200 mg/dL) and acidosis (pH <7.3 or bicarbonate <15 mmol/L) are the defining biochemical characteristics of DKA. The presence of ketosis is important to document to confirm that DKA is the cause of a child's acidosis. In addition to these findings, several other biochemical features of DKA are consistent with the diagnosis. Electrolyte depletion is a prominent feature of DKA that requires close attention and meticulous treatment (Table 354-1).

### Sodium

Sodium concentrations are commonly low at the initial evaluation. Hyponatremia during DKA is the result of the combined effect of renal sodium losses and dilutional effects. As dehydration from the osmotic diuresis ensues, sodium is lost in excess through the kidney. In addition, hyperglycemia and the elevation of other osmotically active solutes (blood urea nitrogen [BUN] and ketone bodies) provide a gradient between the intracellular and extracellular spaces such that water is drawn into the extracellular space, resulting in a dilutional effect and exhibiting as a low serum concentration. The most commonly used correction factor for hyponatremia has been to add 1.6 mEq/L to the measured sodium concentration for every 100 mg/dL of glucose over the normal range. A study in children with DKA showed a decline of approximately 1.6 to 1.8 mmol/L in sodium concentration per 100 mg/dL increase in serum glucose level. Studies in adults have reported different findings for sodium correction, ranging from a decline of 1.35 to 2 mmol/L per 100 mg/dL to 2.4 to 4 mmol/L per 100 mg/dL. Pseudohyponatremia may also be seen in

patients with significant elevations in plasma lipid concentrations. Insulin is a stimulator of lipoprotein lipase, which is necessary for the clearance of triglycerides from the blood. DKA is a state of inadequate insulin, and hyperlipidemia is not an uncommon finding. Sodium is primarily a part of the aqueous fraction of blood, and when the lipid fraction is significantly elevated, the result is apparent hyponatremia (pseudohyponatremia). Because some laboratory methods take this into account when measuring sodium, such as direct potentiometry using an ion-selective electrode, primary care physicians need to know the method used by the laboratory to determine if pseudohyponatremia is contributing to this biochemical abnormality. Accurate assessment of the sodium concentration is necessary to determine appropriate fluid management. It is important to note that a lower than expected rate of rise in sodium concentration during the treatment of DKA has been associated with a higher risk of cerebral edema.

### Potassium

Potassium is primarily an intracellular electrolyte that becomes depleted in children with DKA. In a state of metabolic acidosis, excess hydrogen ions are exchanged for intracellular potassium, which is then excreted through the kidneys. Additional potassium may be lost through the gastrointestinal tract if vomiting occurs. Because of the multiple factors influencing potassium in a patient with DKA, serum potassium levels may vary at presentation and during treatment. However, even if the initial serum potassium concentration is elevated, DKA represents a state of total body potassium depletion as intracellular stores are reduced. At the initial evaluation, potassium levels are typically normal or elevated. When treatment with insulin is begun, potassium shifts to the intracellular compartment, resulting in a decrease in the measured potassium concentration. The resulting profound hyperkalemia or hypokalemia may lead to cardiac arrhythmias, and this electrolyte must be monitored closely and replaced appropriately.

### Phosphorus

Phosphorus is another predominantly intracellular electrolyte that becomes depleted during DKA. The mechanism is similar to that of potassium with the primary loss occurring through the kidneys. Children with DKA may have profound hypophosphatemia that may only become apparent during therapy.

### Other Laboratory Components

An assessment of renal function and dehydration should be performed, including the measurement of BUN and creatinine. These values are typically elevated in a pattern consistent with a prerenal state. Insulin and C-peptide concentrations are generally low in children with newly diagnosed T1D. In the context of uncontrolled diabetes, an elevated serum  $\beta$ -hydroxybutyrate (>3.0 mmol/L) is another helpful diagnostic tool. Although antibody levels against islet cell antigens and insulin are often elevated at the time of diagnosis, they are not useful in the diagnosis or management of DKA. The principles of managing DKA are the same regardless of diabetes type.

## MANAGEMENT

The management of DKA should be focused on correcting the metabolic disturbances while preventing potential complications. The major complications that arise during the treatment of DKA include cerebral edema and hypoglycemia. An increased risk of venous thrombosis has also been associated with DKA, especially in children with a central venous catheter. The effective treatment of DKA includes insulin administration and fluid and electrolyte replacement. Many algorithms have been proposed to assist the physician in the management of DKA. The following principles have been used successfully. However, it must be stressed that no single protocol is appropriate for all children. Specific therapy must be designed according to the clinical circumstances and coexisting diseases, such as infection, which should be treated concomitantly.

### Assessment and Disposition

The initial assessment of a child with DKA should include an estimation of the severity of disease (Table 354-2). The child's cardiovascular and respiratory status should be evaluated and addressed immediately if compromise is present. Signs of neurologic dysfunction should prompt evaluation for cerebral edema, which can be present before any therapeutic intervention. The laboratory assessment should include measurement of the child's blood glucose, pH, bicarbonate, serum  $\beta$ -hydroxybutyrate or urine ketones, and electrolyte (sodium, potassium, chloride, phosphorus, and calcium) levels. A coexisting illness often contributes to the precipitation of DKA; additional studies including cultures (blood, urine, and cerebral spinal fluid) should be obtained when clinically indicated. Urine should also be assessed for glucose and ketones.

Children with mild DKA may not exhibit any clinical findings of dehydration. In many children with established diabetes, mild ketosis can be managed in the outpatient setting if they are able to maintain oral intake. As a part of chronic diabetes care, children and families should be educated on treatment strategies for mild ketosis. Written education materials and access to a physician experienced in the management of children with diabetes may prevent some emergency department visits and hospitalizations. For children with moderate to severe DKA, admission to a pediatric intensive care unit or general pediatric ward is

indicated. Familiarity with the level of care available within a particular institution is essential for the proper placement of the child. Most children with severe DKA require a level of care offered only in an intensive care setting. However, some hospitals are equipped to manage moderate ketoacidosis on a general pediatric ward.

### Fluid Replacement

Children with moderate to severe DKA are generally considered to be between 5% and 10% dehydrated, with calculations based ideally on the child's presenting weight. Ten to 20 mL/kg intravenous fluids are suggested for initial fluid replacement. The American Diabetes Association (ADA) consensus statement and ESPE/PES recommend isotonic solutions such as lactated Ringer's solution or 0.9% saline, which are commonly used for the treatment of dehydration or hypovolemia from any cause. Additional fluid resuscitation may be required in some patients, but caution must be used, especially for children with signs or symptoms suggestive of cerebral edema. Aggressive fluid resuscitation to manage hemodynamic instability is rarely required even for children with severe DKA. In this setting, other causes of hypotension such as sepsis should be considered. The goal of initial fluid resuscitation is not to replace the entire fluid deficit; rehydration should take place over the subsequent 48 hours. In adults and children with DKA, less aggressive rates of fluid replacement have been associated with more rapid correction of the acidosis. A gradual rehydration strategy may reduce the risk of cerebral edema compared with more aggressive fluid administration. Fluid therapy (even before insulin) will result in a reduction of the blood glucose concentration. This reduction is partially the result of a dilutional effect, as well as an improved glomerular filtration rate and increased renal clearance of glucose.

After the initial fluid bolus, the content of the intravenous fluid should be changed to address additional electrolyte abnormalities that may be present and to prevent hyperchloremic metabolic acidosis that may occur if isotonic saline solutions are continued. The ADA and ESPE/PES guidelines suggest that rehydration should take place over at least 48 hours and that the rate of fluid administration should rarely exceed 1.5 to 2 times maintenance fluids requirements. This should be accomplished using a lower tonicity fluid such as 0.45% saline unless the development of cerebral

**Table 354-2** Assessment of the Severity of Diabetic Ketoacidosis

	MILD	MODERATE	SEVERE
Sensorium	Alert	Drowsy, lethargic	Obtundation, coma
Hyperpnea	Absent	Mild	Severe
Hydration	No dehydration	Mild to moderate (3%–5%)	Severe (>5%)
Plasma bicarbonate	>16–18 mEq/L	>10 mEq/L	<10 mEq/L
Anion gap	18–20 mEq/L	<20–25 mEq/L	>25 mEq/L

Modified from Schwenk WF 2nd, Haymond MW. Treatment of diabetic ketoacidosis in children and young adults. *Prim Care*. 1983;10(4):663–676. Copyright © 1983, Elsevier, with permission.

edema requires higher tonicity fluid. The ESPE/LWPES also recommends that urinary losses not be added to the calculated fluid requirement. Because total body stores of potassium are invariably depleted, potassium should be added to the intravenous solution when the potassium concentration is normal or low and urine flow has been established. If the initial potassium concentration is low, potassium should be replaced before initiating insulin therapy to prevent potentially life threatening hypokalemia. When the child transitions to oral intake, after the correction of the acidosis, intravenous fluids should be reduced or discontinued accordingly.

### Insulin Therapy

#### Delivery

Insulin is essential to correct the metabolic disturbances present in children with DKA. Intravenous insulin therapy *should be initiated after starting fluid replacement therapy*. The early administration of insulin is associated with an increased risk of cerebral edema. Intravenous regular insulin is the preferred route of administration. Subcutaneous and intramuscular insulin have been used successfully in the treatment of DKA. However, these modes of insulin delivery should only be used when intravenous access is not possible, especially in severely dehydrated children in whom insulin absorption may be impaired because of poor circulatory status. Intravenous insulin can be titrated frequently if necessary because of its short half-life.

#### Dosing

An initial infusion rate of 0.1 unit/kg/hour of intravenous regular insulin is generally an effective dose. The insulin infusion acts to decrease gluconeogenesis, decrease lipolysis and ketogenesis, and increase peripheral glucose utilization. The blood glucose concentration should not be used alone to determine when to discontinue or decrease the rate of insulin infusion. Ketosis and metabolic acidosis will not correct without adequate insulin administration. The metabolic acidosis often corrects many hours after euglycemia has been restored. For this reason, a constant insulin infusion rate should be used, and glucose should be added to the intravenous fluids when the blood glucose level falls below 250 to 300 mg/dL. An infusion of 5% dextrose may be sufficient for many children. However, higher rates of dextrose infusion may be required to prevent hypoglycemia while the ketoacidosis is resolving. The rate of insulin infusion may need to be increased in some children if the ketoacidosis does not improve or worsens. In this circumstance, additional causes of acidosis or coexisting illnesses should be considered and treated appropriately. In some cases, such as in the very young, the rate of insulin infusion may need to be reduced to 0.05 unit/kg/hour to avoid hypoglycemia. When using a lower rate of insulin infusion, it is important to confirm continued improvement in ketosis.

#### Monitoring

Monitoring the patient's response to therapy frequently is imperative to assess when a change in treatment is required. Such monitoring should include

hourly glucose determinations. Electrolytes, bicarbonate, ketones, and pH should be measured every 2 to 4 hours to ensure correction of the metabolic disturbances. More frequent monitoring is suggested (every 2 hours) with severe DKA and less frequent monitoring (every 4 hours) when improvement in the ketoacidosis has been established. It is also important to perform periodic neurologic exams and monitor the child's neurologic status while managing DKA, particularly in children who are at high risk for developing cerebral edema or those with altered mental status or neurologic findings before or during the initial treatment of DKA.

### Electrolytes

#### Sodium

Sodium concentrations are often low because of the reasons previously mentioned. The isotonic solutions suggested for initial fluid management are intended to increase the intravascular volume and improve the glomerular filtration rate. Sodium depletion is also addressed with this therapy. After the initial fluid administration, the deficit should be replaced with a solution that has a tonicity between 0.45% and 0.9%. A solution of 0.45% saline is often used to prevent excessive sodium and chloride delivery. Excessive isotonic sodium chloride may result in hyperchloremic metabolic acidosis. On the other hand, some authors have suggested that the failure of an increase in the sodium concentration with therapy may be associated with a higher risk of developing cerebral edema. Therefore, sodium concentrations should be monitored closely.

#### Potassium

Potassium concentrations may be elevated, normal, or low before the initiation of therapy in children with DKA. The concentration likely depends on several factors, including the severity and duration of DKA and the presence of gastrointestinal losses caused by vomiting. In children with significantly elevated potassium concentrations, an electrocardiogram should be obtained to check for the presence of a T wave abnormality that occurs in the context of hyperkalemia. An EKG should also be checked if there are delays in obtaining the first electrolyte measurements. With the initiation of insulin therapy, potassium concentrations invariably decline and may become normal or low. Insulin facilitates the intracellular transport of potassium, and the correction of acidosis also results in the exchange of intracellular hydrogen for extracellular potassium, leading to further reductions in potassium concentrations. Adding 20 mEq/L potassium acetate and 20 mEq/L potassium phosphate to 0.45% saline works well in most patients. This combination of salts prevents excess chloride while replacing not only potassium, but also phosphorus, which is often depleted. This solution is a safe and effective means to prevent profound hypokalemia. Potassium should be replaced after the initial isotonic fluid bolus has been given, the serum potassium concentration becomes normal or low, and urine output is established. Potassium levels should be monitored closely and therapy adjusted according to the individual child's needs. If the initial potassium concentration is low, potassium should be

replaced before initiating insulin therapy to prevent potentially life threatening hypokalemia.

### Phosphorus

Phosphate depletion occurs as a result of many of the same mechanisms as potassium depletion. Phosphate concentrations may also be variable before the initiation of therapy. Hypophosphatemia may become profound as intracellular phosphate transport from the extracellular space is facilitated by insulin. Phosphate replacement in the treatment of children with DKA has not been shown to provide clinically important improvements in outcome or to eliminate significant complications. However, the possibility exists of a decrease in oxygen delivery to tissues caused by a shift of the oxyhemoglobin dissociation curve to the left. The addition of potassium phosphate to the rehydration solution is safe and effective at maintaining a normal or near-normal phosphate concentration. If phosphate therapy is used, then serum calcium concentrations should be monitored, because hypocalcemia may occur.

### Bicarbonate

A recent systematic review concluded that the current evidence does not support the use of bicarbonate in the emergent treatment of DKA, especially in children. However, the studies on which the evidence was based were retrospective studies because of the lack of randomized trials in children. In addition, there were no studies on patients with severe profound DKA (pH < 6.9). The current recommendation based on the consensus statement from the ESPE/PES and the International Society of Pediatric and Adolescent Diabetes 2009 advises cautiously administering bicarbonate in cases of profound acidosis, as insulin administration and correction of the underlying metabolic abnormalities is the safest and most effective way to restore bicarbonate levels. Use of bicarbonate in children with DKA may not be appropriate for several reasons. The ketoacidosis can be completely corrected by the administration of intravenous fluids and insulin. Treatment with bicarbonate results in additional sodium administration that may not be required. Paradoxical central nervous system acidosis that may occur as a result of bicarbonate treatment is a potential concern. Bicarbonate therapy has also been associated with an increased risk of cerebral edema. Despite these concerns, some children with cardiovascular dysfunction caused by severe acidosis or hyperkalemia (or both) may benefit from cautious alkali administration.

### Converting to Subcutaneous Insulin

Converting to subcutaneous insulin should be considered when the serum bicarbonate level is greater than 16 to 18 mmol/L (or pH is greater than 7.3) and the child is able to begin oral intake. If DKA has occurred in a child with a previous diagnosis of diabetes, the home insulin regimen may serve as a guide in choosing initial subcutaneous insulin doses and the type of program to use (split-mixed vs multiple daily injection vs continuous subcutaneous insulin infusion). For children with newly diagnosed diabetes, 0.5 to

1.0 units/kg/day in divided doses is appropriate. Frequently, adjustments to the initial doses are necessary depending on the child's meal plan, level of activity, and pubertal status. Children with and without diabetes have increased insulin requirements during puberty compared with prepubertal children. Additional details regarding subcutaneous insulin therapy are discussed in Chapter 241, Diabetes Mellitus.

### COMPLICATIONS: CEREBRAL EDEMA

The reported mortality rate in children with DKA is low (<0.5%). Most of these deaths have been in those who developed clinically apparent cerebral edema. The incidence of clinically apparent cerebral edema in children has been estimated to be approximately 1%. Some, but not all, studies suggest that the incidence of subclinical cerebral edema is higher when using imaging criteria to diagnose the condition. In adults, coexisting conditions such as myocardial infarction contribute to a larger percentage of the mortality associated with DKA.

Although cerebral edema is a rare complication of DKA, the consequences are severe. Several studies in children have reported a mortality rate of approximately 20% to 25% for those who developed cerebral edema. A significant proportion of those who survive have permanent neurologic consequences. The symptoms of cerebral edema attributed to increased intracranial pressure include a decreased level of consciousness, elevated blood pressure, and bradycardia. Nonspecific symptoms such as headache may also be present, and a high index of suspicion should be maintained to identify this potentially fatal condition early. If these clinical findings are encountered at any time during the treatment of DKA, prompt assessment, including imaging of the head, should be undertaken.

The precise etiology of cerebral edema is not clear; however, several potential risk factors have been identified (Box 354-3). Few data are available to establish optimal therapy for cerebral edema associated with DKA. If cerebral edema occurs, the ESPE/PES consensus statement recommends that the rate of fluid administration be reduced. Intravenous mannitol may be given and repeated after 2 hours if clinically indicated. Case reports of improvement in cerebral edema with this therapy have been published. However, a randomized clinical trial with a small number

#### BOX 354-3 Risk Factors for Cerebral Edema

- Lower partial pressure of arterial carbon dioxide at presentation
- Severity of dehydration (higher initial BUN)
- Smaller rise in serum sodium during treatment
- More severe acidosis at presentation
- New-onset diabetes
- Treatment with bicarbonate
- Younger age
- Longer duration of symptoms before presentation
- Insulin administration in the first hour of fluid treatment

of children found that the rate of fluid infusion did not change the MRI measures of cerebral edema in children with DKA. Hypertonic saline has also been suggested as an alternative to the use of mannitol in the treatment of children with cerebral edema. If intubation is required, then hyperventilation should be avoided, because this has been associated with worse outcomes. Frequent neurologic examinations should be performed in children with DKA in an attempt to identify and intervene early. Because cerebral edema can be present before therapy for DKA, prevention of DKA may be the only effective strategy to prevent this potentially devastating complication.

## PREVENTION

In children with established T1D, ketoacidosis is largely preventable with proper attention to glycemic control, especially during times of illness. Most children develop DKA because of the omission of insulin, which may occur for a variety of reasons, including financial constraints or a lack of knowledge regarding proper management during illness. This finding emphasizes the importance of ongoing diabetes education for the children and their families to help them understand the factors that lead to DKA in an effort to prevent its occurrence.

Few prospective studies have been performed with the goal of preventing DKA in children with newly diagnosed diabetes. There were 2 large studies (in Italy and Australia) that investigated the effects of raising public awareness regarding diabetes and found significantly fewer episodes of DKA at the time of diagnosis in the studies' regions compared with surrounding communities (64% reduction in the rate of DKA in the Australian study). Raising public awareness of the symptoms of diabetes may be a cost-effective way to prevent this potentially fatal illness.

In children with established diabetes, the cause of DKA cited most often is the omission of insulin, which is a preventable problem. Effective education should be a part of any comprehensive diabetes program and has the potential to decrease the rates of recurrent DKA. Clinical experience and a review of the literature indicate that a small percentage of patients with diabetes account for a disproportionate number of episodes of DKA. Interventions targeted at this high-risk population seems appropriate. For further information, see Chapter 241, Diabetes Mellitus.

### WHEN TO REFER

- When facilities to provide frequent patient assessment (clinical and laboratory) are not available
- When a physician experienced in the diagnosis and treatment of DKA is not available

### WHEN TO ADMIT

- Patients with moderate to severe DKA
- Patients with dehydration or those who are unable to maintain adequate oral intake
- Most patients with newly diagnosed diabetes regardless of the severity of ketoacidosis

## Chapter 355

# DISSEMINATED INTRAVASCULAR COAGULATION

Steven W. Pipe, MD; Anjali A. Sharathkumar, MBBS, MD, MS

## DEFINITION

Disseminated intravascular coagulation (DIC) is a pathologic syndrome that arises from a heterogeneous group of medical disorders. It is characterized by simultaneous activation of both clotting and fibrinolysis. This action leads to widespread intravascular deposition of fibrin with resultant thrombotic end-organ complications and consumption of platelets and coagulation proteins, resulting in severe bleeding. DIC is always a secondary phenomenon and not a disease entity in its own right. The clinical expression of DIC varies and may be displayed by laboratory abnormalities alone or in combination with hemorrhagic and thrombotic complications. Because of the variable clinical manifestations and heterogeneity of primary disorders associated with the development of DIC, this entity has been recognized under various different names, including *consumptive coagulopathy*, *hemorrhagic syndrome*, *defibrination syndrome*, or *consumptive thrombohemorrhagic disorder*.

## INCIDENCE

Given that DIC often occurs in combination with sepsis, trauma, and systemic inflammatory syndrome, the precise incidence of this condition is difficult to assess. The frequency of DIC in hospitalized children is approximately 0.4% to 1%. The incidence of DIC according to the underlying disease process is not known. Infection is the most common etiologic factor, contributing to DIC in almost 95% of children; multiorgan dysfunction occurs in almost 85% of children. Associated comorbidities, such as the underlying disease, multiorgan dysfunction, and respiratory failure, determine the outcome of DIC.

## PATHOGENESIS

### Physiologic Features of Hemostasis

Improved understanding of molecular mechanisms involved in the physiologic features of hemostasis has

led to better understanding of the pathogenesis of DIC. In healthy individuals, physiologic hemostasis is tightly controlled as a balance of forces promoting and impeding coagulation and fibrinolysis. Normally, in response to injury, coagulation is limited to the site of vascular injury. After such injury, platelets adhere to the exposed collagen mediated by the von Willebrand factor, which activates platelets. A signaling cascade within activated platelets causes release of platelet granule contents and facilitates thrombin generation on their surface. As a result of platelet activation and thrombin formation, platelets aggregate, leading to a primary hemostatic plug. Simultaneously, the extrinsic pathway of coagulation is activated. Tissue factor (TF), up regulated on endothelial cells adjacent to the vascular injury and present on monocytes, forms a complex with circulating factor VII, resulting in the activation of factor VII and the formation of a TF–factor VII/VIIIa complex. This complex then activates factors IX and X on the negatively charged phospholipid surface of platelets. Factor Xa, in turn, converts prothrombin to thrombin, the major procoagulant. Thrombin generation is greatly amplified through activation of a feedback loop (intrinsic pathway) through activation of factor XI, which, in turn, activates more factor IX. Thrombin also activates the coagulation cofactors, factor VIII and factor V. Activated factors VIII (VIIIa) and V (Va) increase the efficiency of factor Xa and thrombin generation, respectively, by several orders of magnitude. Once thrombin is generated, it converts soluble fibrinogen to insoluble fibrin. Fibrin monomers polymerize, and adjacent fibrin monomers are cross-linked between their respective D domains by factor XIIIa. The insoluble, cross-linked fibrin enmeshes the platelet plug, forming a secondary hemostatic plug.

This process is kept in check by anticoagulant and fibrinolytic pathways. TF pathway inhibitor (TFPI) is an endogenous anticoagulant protein that binds to and inactivates the TF–factor VIIa complex and factor Xa. Thrombin is quickly inactivated by antithrombin (AT) by forming thrombin-AT (TAT) complexes that are rapidly cleared from plasma. Thrombin also binds to thrombomodulin (TM) on the endothelial surface, abrogating its procoagulant activity. Thrombin-TM complexes, in turn, activate protein C, which, in the presence of its cofactor, protein S, proteolytically inactivates factors VIIIa and Va, dampening further thrombin generation. Fibrinolysis is promoted by thrombin-induced tissue-type plasminogen activator release from endothelial cells, generating plasmin. Plasmin will degrade both soluble fibrinogen and insoluble fibrin. The resultant fragments can be measured as fibrinogen-fibrin degradation products (FDPs). When plasmin cleaves cross-linked fibrin, it liberates a soluble D-dimer. Plasmin generation is also regulated through inhibition by plasminogen activator inhibitor type 1. As shown in Figure 355-1, thrombin generation plays a crucial role in interconnecting all of these pathways.

### Primary Events of Disseminated Intravascular Coagulation

In DIC, the normal physiologic feature of coagulation is disturbed by the simultaneous action of 4 mechanisms:

increased thrombin generation, suppressed physiologic anticoagulant pathways, activation and subsequent impairment of fibrinolysis, and activation of the inflammatory pathway. Figure 355-2 illustrates the primary events involved in DIC. During an inciting event such as sepsis, monocytes and endothelial cells are injured by toxic substances that are elaborated during the disease process. They generate TF, which activates the coagulation cascade (see Figure 355-1). Continuous activation of coagulation leads to an unregulated and explosive generation of thrombin, which, in turn, depletes clotting factors and platelets and activates the fibrinolytic system. Activation of clotting leads to generalized fibrin deposition and microthrombi formation. These microthrombi deposit in various organs, leading to tissue ischemia and multiorgan failure. Deposition of fibrin in microvasculature also leads to mechanical fragmentation of erythrocytes, causing microangiopathic hemolytic anemia (Figure 355-3; see also Figure 355-1). Impaired function of the physiologic anticoagulant pathways can amplify thrombin generation and contribute to fibrin formation. Plasma levels of AT are reduced in patients with sepsis, and the activated protein C system may be significantly depressed through consumption and down regulation of TM expression on the endothelium. An initial hyperfibrinolytic response causes clot lysis, contributing to cutaneous hemorrhages and bleeding into the internal organs. Subsequently, however, increases in the plasma levels of plasminogen activator inhibitor type 1 (PAI-1) can suppress fibrinolytic activity. Finally, stimulation of endothelial cells to synthesize proinflammatory cytokines can promote further coagulation activation. This is accompanied by vasodilatation and loss of tight junctions between endothelial cells, leading to capillary leak and shock. Thus, the overall clinical manifestation of DIC depends on simultaneous activation of the inflammatory cascade, coagulation cascade, and involvement of endothelial microvasculature.

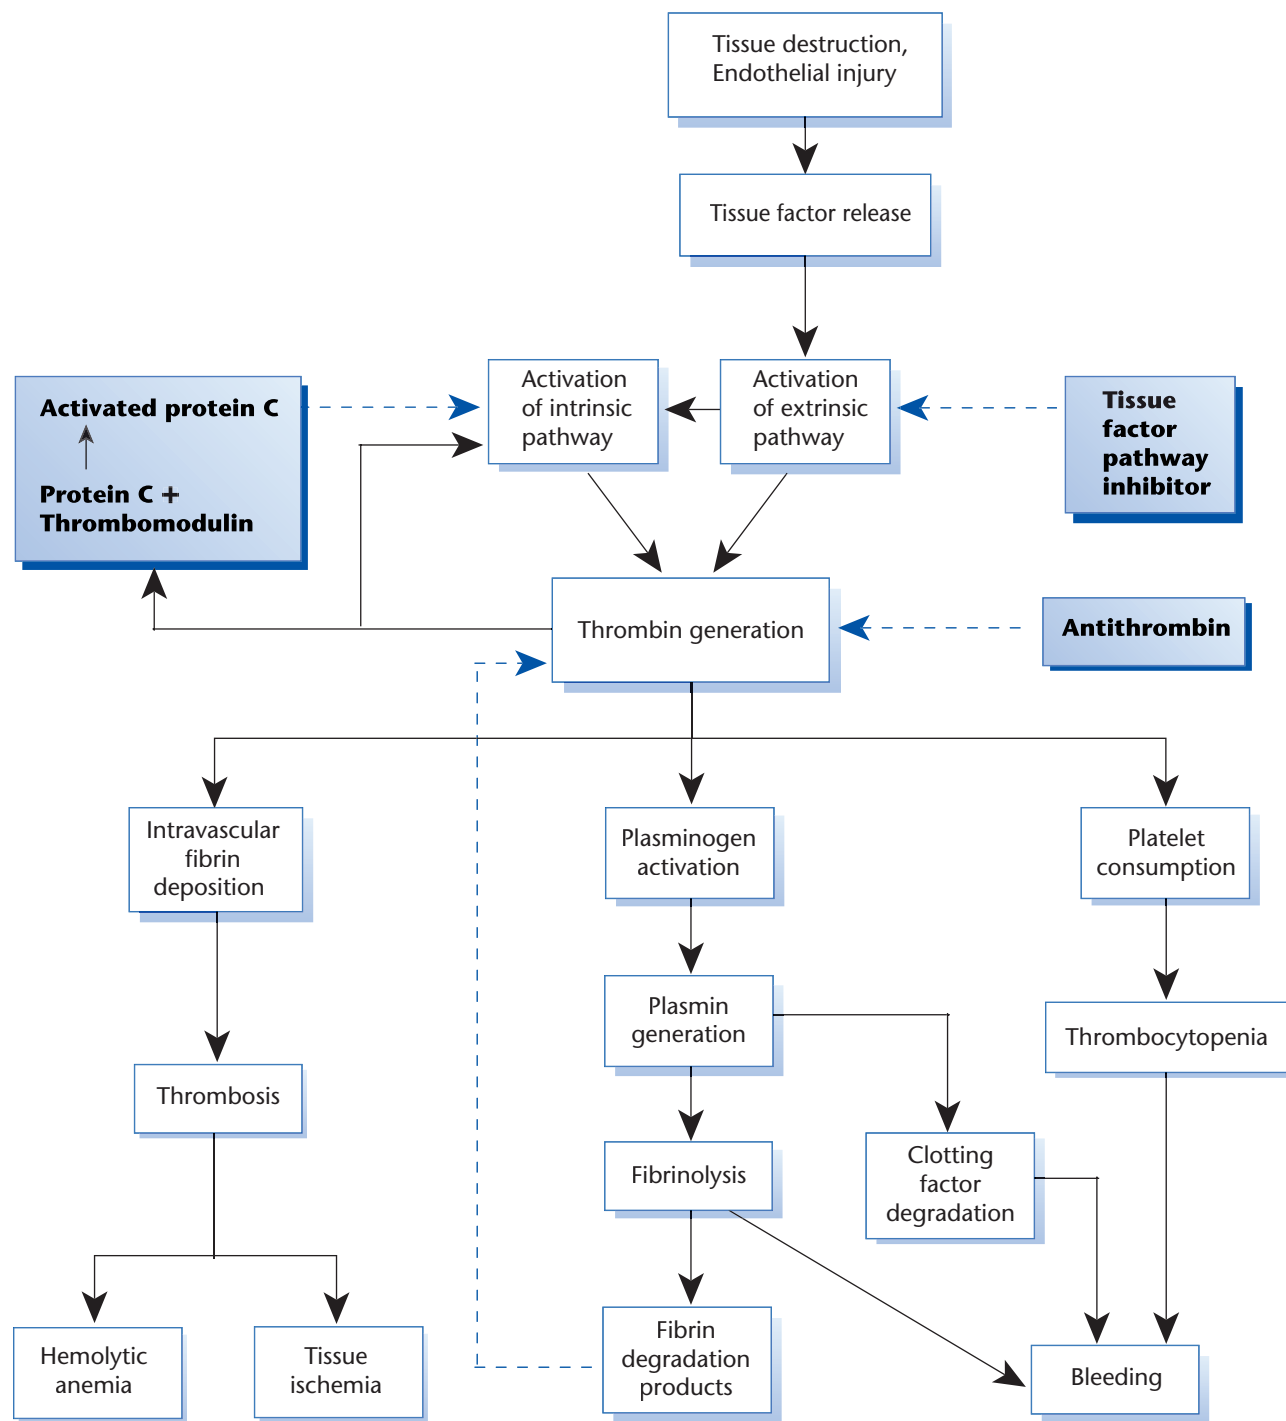

## DIFFERENTIAL DIAGNOSIS

The clinical manifestations and laboratory abnormalities of several conditions may mimic or may be indistinguishable from DIC, yet may require unique diagnostic evaluations and management. Commonly encountered systemic diseases that present with clinical features of DIC are discussed in the following text.

### Fulminant Hepatic Failure

Synthesis of coagulation proteins (factors II, V, VII, IX, X, and fibrinogen) and inhibitors of coagulation (AT III, protein C, and protein S) is affected in hepatocellular failure. Associated hypersplenism contributes to thrombocytopenia. Bleeding manifestations predominate. The main treatment strategy is supportive care and blood component therapy to provide deficient coagulant proteins until the underlying disease is treated.

Blue color indicates inhibitors of coagulation

**Figure 355-1** Pathophysiological mechanism of disseminated intravascular coagulation.

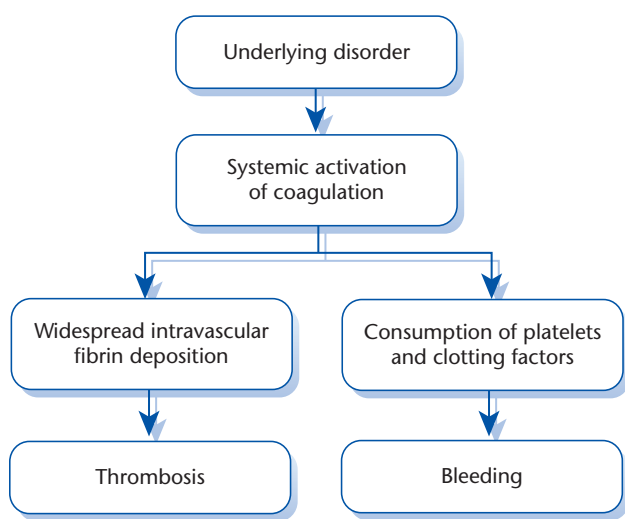

### HELLP Syndrome

HELLP (hemolysis, elevated liver function tests, and low platelets) syndrome is commonly associated with pregnancy. Clinical and laboratory features are similar to DIC, but hypertension is relatively common in HELLP syndrome. In severe cases, the treatment is to

promptly deliver the fetus and placenta along with supportive care.

### Chronic Disseminated Intravascular Coagulation

Chronic DIC, also known as *Trousseau syndrome*, occurs rarely in children. Chronic DIC is commonly

**Figure 355-2** Primary events in disseminated intravascular coagulation.

**Figure 355-3** Blood smear of a patient with disseminated intravascular coagulation showing schistocytes (arrow).

associated with malignancies such as mucinous adenocarcinomas, ovarian cancer, and pancreatic tumors. It exhibits as migratory thrombophlebitis, arterial and venous thrombosis, hemorrhagic diathesis, and laboratory values consistent with DIC. The mainstay of treatment is long-term anticoagulation with heparin therapy until the underlying condition is resolved.

### Massive Transfusion

Massive transfusion has been defined as the replacement of more than 1 blood volume in 24 hours or the replacement of 50% of the total blood volume within 3 hours. For example, considering the blood volume of a 30-kg child to be roughly 2,400 mL, such a transfusion would require approximately 8 units of blood products over 24 hours or 4 units over 3 hours. Hemostatic failure can result from dilution of clotting factors or acquired

platelet dysfunction. Hemostatic tests typically show prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT), reduced fibrinogen, and thrombocytopenia. Clinical bleeding associated with hemostatic failure can be managed first with prompt transfusion with cryoprecipitate and fresh frozen plasma (FFP). However, platelet transfusion may be required if bleeding persists. Recent randomized, placebo-controlled, double-blind trials have suggested a benefit of recombinant factor VIIa in the management of excessive perioperative bleeding.

### Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is considered a primary disorder in which platelet-rich thrombi form within the microvasculature, leading to tissue ischemia. TTP is caused by congenital (Upshaw-Schulman syndrome) or acquired deficiency of a von Willebrand factor-cleaving protease (ADAMTS13). Patients can exhibit fever, thrombocytopenia, microangiopathic hemolytic anemia, renal failure, and neurologic signs. Screening coagulation tests (PT, PTT) and FDPs are usually normal. Treatment is plasmapheresis and supplementation of ADAMTS13 protease through FFP infusion.

### Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS), the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency, is clinically similar to TTP and is often confused with DIC. HUS occurs in children younger than 3 years. Most cases are caused by Shiga toxin-producing strains of *Escherichia coli*, most often the O157:H7 subtype. Acute mortality in HUS is 3% to 5%, mostly from central nervous system involvement, cardiac failure, or multiorgan failure. Laboratory findings in HUS include microangiopathic hemolytic anemia, with a hemoglobin level of less than 10 g/dL and a negative direct antiglobulin (Coombs) test. HUS is a clinical diagnosis; the presence of schistocytes and helmet cells on the blood smear suggests mechanical trauma. Typical findings accompanying hemolysis include increased indirect bilirubin, decreased haptoglobin, and increased lactate dehydrogenase values. Thrombocytopenia (platelet count  $<100 \times 10^3/\mu\text{L}$ ) is usually present and can be severe ( $<20 \times 10^3/\mu\text{L}$ ). Screening coagulation test (PT, PTT) results are normal. Urinalysis shows hematuria and proteinuria. Blood urea nitrogen and creatinine concentrations are elevated, and the albumin concentration may be decreased from protein loss in the gastrointestinal tract. Management is primarily supportive, and includes renal replacement therapy.

### EVALUATION

Disseminated intravascular coagulation is a clinical diagnosis based on the evaluation of laboratory results in a patient with a clinical condition known to be associated with DIC (Box 355-1).

### Relevant History and Physical Examination Findings

Clinical manifestations of DIC include bleeding, thrombosis, or both. However, in general, bleeding manifestations predominate. Bleeding is typically

**BOX 355-1 Causes of Disseminated Intravascular Coagulation in Children****SEPSIS OR SEVERE INFECTION**

- Bacterial (eg, methicillin-resistant *Staphylococcus aureus*, streptococci)
- Viral (eg, HIV, cytomegalovirus, varicella, hepatitis viruses)
- Fungal (eg, *Histoplasma*)
- Parasitic (eg, malaria)

**TRAUMA**

- Polytrauma
- Neurotrauma
- Fat embolism

**ORGAN FAILURE**

- Severe pancreatitis
- Liver cell failure

**MALIGNANCY**

- Acute promyelocytic leukemia
- Lymphoproliferative disorders
- Hemophagocytic lymphohistiocytosis
- Solid tumors

**OBSTETRICAL CALAMITIES**

- Dead fetus syndrome
- Abruptio placentae
- Amniotic fluid embolism

**VASCULAR ABNORMALITIES**

- Kasabach-Merritt syndrome
- Large vascular aneurysms

**IMMUNOLOGIC CONDITIONS**

- Systemic lupus erythematosus
- Autoimmune hemolytic anemia
- Crohn disease
- Ulcerative colitis
- Transfusion reactions
- Transplant rejection

**MISCELLANEOUS**

- Snake bites
- Recreational drugs
- Poisoning
- Burns
- Massive transfusions

acute and occurs from multiple sites. Bleeding from venipuncture sites and intravascular access sites, such as intra-arterial lines or surgical wounds, is an important early indication of DIC. Mucocutaneous bleeding, such as petechiae, purpura, epistaxis, gum bleeding, bleeding after tracheal suctioning, gastrointestinal bleeding, and hematuria, is commonly observed. In more advanced cases, internal bleeding in vital organs such as the brain, lung, heart, and organs of the gastrointestinal system may constitute a medical emergency, with patients experiencing raised intracranial pressure, brain herniation, respiratory compromise, or shock. Generalized microvascular thrombosis may produce purpura fulminans, peripheral acrocyanosis, and pregangrenous changes in digits, genitalia, and nose. Microvascular thrombosis in various organs further contributes to multi-organ failure and hemodynamic instability. DIC in neonates carries some unique considerations as discussed in Chapter 103, The Newborn With Hematologic Abnormalities.

A practical approach to categorize and understand many clinical presentations of DIC is by rate of progression (acute or chronic), extent (localized or systemic), and chief clinical manifestations (thrombotic or hemorrhagic, with or without progressive organ dysfunction). The International Society of Thrombosis and Haemostasis (ISTH) Subcommittee of the Scientific and Standardization Committee (SSC) recommended classifying DIC into 2 broad categories: overt or decompensated DIC, and non overt or stable hemostatic function, based on a scoring system. This scoring system is currently widely

used in adult patients. Details of this scoring system are described in the Clinical Monitoring section.

**Laboratory Testing**

The role of laboratory tests in DIC is to show evidence of a consumptive coagulopathy with activation of the fibrinolytic cascade. A complete blood cell count may show moderate-to-severe thrombocytopenia with or without anemia. Thrombocytopenia is present in approximately 50% of patients and suggests consumption of platelets, whereas anemia might be caused by bleeding or mechanical destruction of red blood cells. Presence of fragmented red blood cells (schistocytes) on blood smear confirms the diagnosis of microvascular angiopathy (see Figure 355-3). Screening tests for the extrinsic and intrinsic coagulation cascade, such as the PT and PTT, respectively, are prolonged in 50% to 60% of patients, reflecting consumption of many coagulation proteins, including prothrombin; factors V, VII, and VIII; and fibrinogen. FDPs and D-dimers are both increased in concentration in most patients with DIC, suggesting activation of the fibrinolytic process.

The most sensitive tests for diagnosis of DIC are markers of endogenous thrombin generation: prothrombin fragment 1.2 and TAT complexes. Prothrombin fragment 1.2 is released when thrombin is generated from prothrombin. TAT complexes are generated by binding of thrombin with its inhibitor AT.

In practice, although the standard assays are relatively rapid and simple to perform, changes in these test results do not always occur at the same time, and

### BOX 355-2 Treatment of Disseminated Intravascular Coagulation

- Aggressive treatment of the underlying cause
- Obtaining reliable venous access and considering central venous access
- Possible multiorgan support required
  - Ventilatory support
  - Circulatory resuscitation or inotropic agents
  - Hemodialysis
- Blood product support if evidence of active bleeding
  - Platelets if less than  $50 \times 10^9/L$
  - Fresh frozen plasma if clotting times prolonged (dose: 15 mL/kg)
  - Cryoprecipitate to keep fibrinogen more than 100 mg/dL (dose: 1–1.5 bags/10 kg)
  - Packed red blood cell transfusion (dose: 10 mL/kg)
  - Recombinant factor VIIa for intractable bleeding or volume overload (dose: 75 mcg/kg every 2 hours)
  - Recombinant human activated protein C in desperate situations with severe sepsis and multiple organ failure, provided platelet count is more than  $50 \times 10^9/L$  (dose: 24 mcg/kg per hour for 24–72 hours)

laboratory values change rapidly based on the patient's clinical status, which may create confusion in patient management. These changes also make the diagnosis of DIC at an early stage particularly difficult.

## MANAGEMENT

Most children with DIC will either already be in the intensive care unit because of their underlying disease or require admission because of the disease complications that can occur. The fundamental principle of DIC treatment is the specific and vigorous treatment of the underlying disorder. In some cases, DIC will completely resolve within hours after resolution of the underlying condition (eg, in cases of DIC induced by placental abruption or intrauterine fetal demise). However, in other cases, supportive measures are required to control the DIC until the underlying condition is resolved (eg, the use of all-trans-retinoic acid and chemotherapy for the treatment of acute promyelocytic leukemia and DIC). Recent insights into mechanisms that contribute to DIC have been helpful in developing new preventive, supportive, and therapeutic management strategies. However, therapeutic decisions remain controversial and need to be individualized according to the underlying basis for the DIC and severity of the clinical symptoms. Consultation with a hematologist (if available) is advisable for management of DIC. Box 355-2 lists the key components of DIC management.

### Clinical Monitoring

The underlying condition, the DIC itself, and response to therapy can rapidly change the clinical manifestations of the disease in children. Therefore, frequent

clinical monitoring along with monitoring of PT, PTT, fibrinogen, and platelet counts may be needed several times per day. Monitoring of other biomarkers of DIC, including D-dimer, prothrombin 1+2, TAT, and FDP levels once every day is usually enough.

The ISTH Subcommittee of the Scientific and Standardization Committee (SSC) on DIC has recommended the use of a scoring system for overt DIC. The ISTH criteria incorporate a 5-step diagnostic algorithm to calculate a DIC score, using simple laboratory tests that are available in almost all hospital laboratories (see Figure 355-4). The presence of an underlying disorder known to be associated with DIC is a prerequisite for the use of the algorithm. For overt DIC, a cumulative score of 5 or more from prolonged PT, reduced platelets and fibrinogen, and elevated fibrin-related markers (eg, D-dimer or FDP) was proposed. A total score of 5 or more is considered compatible with DIC. The sensitivity and specificity of this scoring system are more than 90%. Recent observations have suggested that scoring for rates of change in the PT, platelet count, and D-dimer levels can help identify non overt DIC in the early stages. Although this scoring system is applicable at bedside, it has not yet been validated in the pediatric population. Texas Children's Hospital has modified the ISTH DIC scoring system for clinical use. This system recommends daily monitoring of coagulation parameters to improve the sensitivity of the scoring system. Widespread use of its clinical application is limited at this point, because this scoring system is not validated in large clinical studies.

## Treatment Modalities

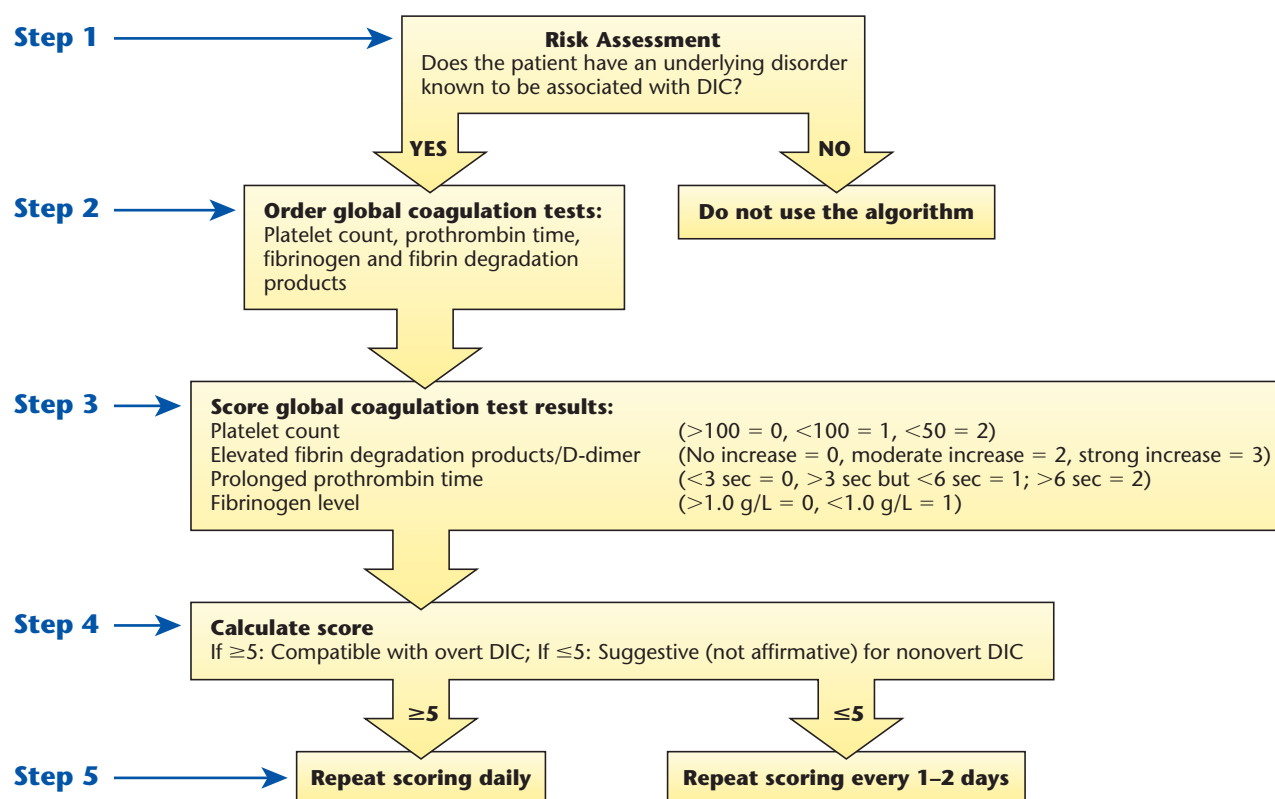

### Blood Component Therapy

Low levels of platelets and coagulation factors may increase the risk of bleeding. Thus, treatment with FFP, fibrinogen, cryoprecipitate, or platelets seems to be a rational therapy for patients with bleeding or those who are at risk for bleeding with significant depletion of these hemostatic factors. However, blood component therapy should not be instituted based on laboratory results alone; it is indicated only in patients with active bleeding, those who require an invasive procedure, or those who are otherwise at risk for bleeding complications. Using large volumes of plasma may be necessary to correct the coagulation defect.

### Anticoagulants

Use of heparin or other anticoagulants seems reasonable to inhibit thrombin generation, considering the central role played by thrombin in DIC. Experimental studies and case reports have shown that heparin can at least partly inhibit the activation of coagulation in sepsis and other causes of DIC. However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in controlled clinical trials. In addition, the safety of heparin treatment is debatable in patients who have DIC and who are prone to bleeding. Hence, using heparin is not a standard of care in overt cases of DIC. Heparin is generally contraindicated in children with overt or suspected bleeding within vital

**Figure 355-4** International Society of Thrombosis and Haemostasis (ISTH) scoring system for overt disseminated intravascular coagulopathy. DIC, disseminated intravascular coagulation. (Based on Taylor FB Jr, Toh CH, Hoots WK, Wada H, Levi M; Scientific Subcommittee on Disseminated Intravascular Coagulation (DIC) of the International Society on Thrombosis and Haemostasis (ISTH). Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. *Thromb Haemost*. 2001;86(5):1327–1330.)

organs such as the central nervous system, or bleeding within closed cavities like the abdomen. However, therapeutic doses of heparin are indicated in patients with clinically overt thromboembolism, chronic DIC, or extensive fibrin deposition, as seen in purpura fulminans or acral ischemia, as long as there is no ongoing major bleeding.

### Restoration of Natural Anticoagulant Pathways

Another therapeutic option that seems appealing is to restore natural coagulation inhibitors such as protein C, protein S, AT, and TFPI inhibitors to physiologic levels. Use of FFP as a source of AT, protein C, and protein S is not practical because of the short plasma half-life of these proteins, specifically proteins C and S, and issues related to volume overload.

Protein C concentrates and AT III concentrates have been used in adults and in a few pediatric trials of DIC in general or meningococemia-associated DIC in particular. Although the double-blind, placebo-controlled, phase III trial of recombinant human activated protein C worldwide evaluation in severe sepsis (known as the PROWESS trial) was successful, showing a significant decrease in mortality when compared with the placebo group in an adult population, those results could not be replicated in children. A large-scale randomized

clinical trial in children with sepsis recruited 477 children (ages 28 days to 17 years) but showed no benefit of activated protein C concentrates. The subanalyses showed that the safety profile of recombinant activated protein C concentrates was unacceptable in infants younger than 60 days because of increased incidence of intracranial bleeding. Bleeding is the only recognized adverse effect with this therapy. Maintaining platelet counts above  $30 \times 10^9/L$  is prudent during this therapy. The dose of recombinant activated protein C is 24 mcg/kg per hour.

Clinical trials of AT III concentrates in adult population have failed to show clear benefit in sepsis populations. Although there are reports about the safety and efficacy of AT concentrates in children, there is hesitancy to use them in clinical practice because of discouraging results from adult studies.

Similar to protein C and AT concentrates, recombinant TFPI and soluble TM concentrates are being evaluated in phase II/III clinical studies in adult populations. Early reports are inconclusive about their efficacy, and more work needs to be done before performing clinical trials in pediatric population.

### Other Agents

Recently, recombinant factor VIIa (rFVIIa) has become an attractive option for controlling bleeding in various

scenarios. In situations in which volume overload is an issue or bleeding persists despite adequate blood component support, use of rFVIIa (75 mcg/kg every 2 hours) has been shown to be effective. High doses of rFVIIa (270 mcg/kg every 2–4 hours) have been shown to inhibit fibrinolysis in patients with severe hemophilia A with inhibitors. Because of the thrombogenic potential of this product, it should be used with caution in children with DIC.

## CONCLUSION

Disseminated intravascular coagulation has been associated with unacceptably high mortality. New information about the pathophysiologic features and treatment of DIC promises new hope of an improved prognosis for this disorder. Understanding the relationship between inflammation and coagulation has led to a conceptual shift in the treatment strategy for DIC. Coordinated clinical efforts are required to study the safety and efficacy of newer agents in the treatment of DIC.

## Chapter 356

# DROWNING AND NEAR DROWNING (SUBMERSION INJURIES)

Lorry R. Frankel, MD

*Drowning* and *near drowning* refer to submersion accidents. *Drowning* is defined as death caused by suffocation within 24 hours after submersion in a liquid medium. *Near drowning* refers to an event whereby a person has survived this initial time period through resuscitative efforts. *Submersion injury* is now the term more commonly used for drowning and near drowning. Drowning remains an important cause of accidental death among children and adolescents, ranking second to motor vehicle accidents as the leading cause of accidental death in this age group. There are over 4,000 pediatric deaths each year attributed to submersion injuries.

Submersion injuries are among the most tragic and catastrophic accidents that can occur to children. Within a matter of minutes, a perfectly healthy child may die from submersion or may be left with severe neurologic injury. Although the mortality rates for submersion injuries have declined, survivors may endure neurologic injuries ranging from a permanent vegetative state to motor and cognitive disabilities.

The most important determinant in the patient's outcome is the patient status following resuscitative measures at the scene of submersion. Patients who are conscious at arrival at a hospital have an excellent chance of intact survival. Pulmonary injury can be managed successfully with newer innovative approaches to mechanical ventilation. Persons with the worst prognoses are those who continue to require resuscitation in the emergency department (ED). This remains true regardless of the age of the patient, duration of submersion, pH at the time of care, or body temperature. The best predictor of outcome is return of normal neurologic function within 24 to 72 hours. It has been well documented that people who do not have a return of cognitive function within 72 hours of the hypoxic episode either do not survive or do so in a persistent vegetative state. Other poor prognostic findings include the continuation of cardiopulmonary resuscitation (CPR) beyond 25 minutes; fixed, dilated pupils; seizures; flaccidity; a Glasgow coma score of less than 5; and decreased cerebral blood flow.

Cold-water submersions that produce severe hypothermia may influence the outcome, but not all victims of hypothermic submersion escape serious neurologic sequelae.

## EPIDEMIOLOGIC CONSIDERATIONS

In the United States, approximately 1,400 drowning deaths occur each year in children younger than 19 years. The groups most at risk include children younger than 5 and boys between the ages of 5 and 19 years. Among those younger than 5, the drowning rate is higher for white children than for black children. The overall outcome for submersion injuries seems to be bimodal, with children either dying or being discharged home. A few children are either discharged home with skilled nursing care or discharged to a long-term or chronic care facility.

The circumstances that surround submersion injuries vary by age and geographic region. Bathtub submersion injuries are more common in children younger than 1 year of age who are left in the care of an older sibling or who are without adult supervision. Child abuse should be suspected when bathtub submersion events occur. Bathtub submersion injuries may be associated with scald burns from hot water. Toddlers are more likely than older children to experience submersion injuries in family swimming pools, hot tubs, or on top of pools by falling into a puddle of water on top of the pool cover. Older children and adolescents may experience submersion injuries during a diving accident. Adolescent and adult drowning incidents are often associated with drinking alcohol or using drugs, which may impair judgment and increase risk-taking behaviors. Portable above-ground pools represent another significant problem in residential settings

for children younger than 5 years. Many incidents occur in the child's own yard and usually in the summer months.

Not all submersion injuries are fatal. However, the morbidity may not be inconsequential. For every submersion injury that results in a death within 24 hours, approximately 4 hospital admissions and 14 ED visits occur. Despite efforts to educate children about pool safety, submersion injuries continue to occur. Community education and mandatory barriers around private pools have resulted in a reduction in the number of submersion injuries.

### **PATHOPHYSIOLOGICAL FEATURES OF SUBMERSION INJURIES**

Asphyxia, anoxia, hypothermia, and reperfusion injuries are the hallmarks of submersion injuries. The child initially panics, then holds his or her breath and loses consciousness. During this period, the child may lose cough and gag reflexes and then aspirate large amounts of water. This action produces anoxia, resulting in decreased oxygen delivery to the tissues. The child's heart rhythm becomes abnormal, with evidence of fibrillation and finally asystole. In addition, the child's core temperature begins to drop. Theoretically the type of fluid aspirated affects the circulatory volume and electrolyte balance. Fresh water is hypotonic and is rapidly absorbed across the alveoli, which may result in increased blood volume, hemodilution, a reduction in serum electrolytes, and hemolysis. On the other hand, a submersion injury in salt water may result in hemoconcentration, decreased blood volume, and an elevation in serum electrolytes.

For blood volume to be seriously altered, the patient must aspirate at least 11 mL of fluid per kilogram of body weight; at least twice this amount must be aspirated to result in marked electrolyte changes. However, most children aspirate less than 4 mL/kg of fluid, which means that, practically speaking, little clinical relevance exists to the type of water in which the child is submerged. Most patients who experience near drowning are intravascularly hypovolemic as a result of capillary leak from asphyxia. The effects on the body may be on a single system or multiple systems. In addition to hypovolemia, patients who experience near drowning may experience serious injury to other organ systems, including pulmonary injury with surfactant washout and aspiration of gastric contents or contaminated water contents, central nervous system (CNS) injury resulting from anoxic or ischemic events, myocardial injury, renal impairment, injury to the gut mucosa, and liver function abnormalities.

#### **Pulmonary Effects**

Usually the lungs are the most seriously affected organs. The decrease in the functional residual capacity of the lungs results in hypoxia and hypercarbia. The lung injury may progress from either aspiration pneumonia or simple pulmonary edema with alterations in surfactant to the acute lung injury commonly referred to as *acute respiratory distress syndrome*. The child may have apnea or agonal respirations or may have difficulty with airway protection. Understanding these

changes enables the astute pediatrician to act appropriately to prevent further hypoxic or anoxic injury.

If spontaneous respirations are present, then the pediatrician should first administer oxygen to the child. If the child does not possess the capability to protect the airway, then the airway must be intubated with an endotracheal tube of the appropriate size. Initial ventilatory settings will require enough tidal volume (6–10 mL/kg) or inspiratory pressure to allow for adequate rising of the chest wall. Higher tidal volumes may be associated with ventilator-induced lung injury. Positive end-expiratory pressure (4–8 cm H<sub>2</sub>O) must be used to help alveolar distension. An age-appropriate respiratory rate and a fraction of inspired oxygen of 1.0 should be provided. The child should undergo chest radiography to evaluate the degree of lung injury and to make certain that the endotracheal tube is placed correctly.

#### **Hemodynamic Effects**

The cardiovascular system may be seriously affected as a result of the period of anoxia. Myocardial contractility may be greatly reduced, and the patient may require inotropic support in the form of dopamine, epinephrine, or dobutamine. The goal is to hydrate the child adequately with 20 to 40 mL/kg of isotonic crystalloid or colloid. If the hemodynamic response is suboptimal, inotropes should be added. To accomplish this task safely and effectively, a central venous catheter and an arterial line should be inserted. A double-lumen catheter should be used for the central venous access. The distal port should be used to transduce the central venous pressure (CVP) and the proximal port used to infuse inotropes. The line may be inserted into any one of several vessels (subclavian, internal jugular, external jugular, or femoral).

The child will require continuous monitoring of vital signs and CVP. CVP monitoring enables the physician to better understand the child's volume status, which helps guide fluid administration. An arterial line enables continuous monitoring of the mean arterial pressure, which should be kept in the correct range for age. If the patient continues to struggle with high CVPs and poor cardiac output, then the physician should consider placing a pulmonary artery catheter to measure the wedge pressure, which is a reflection of the true CVP. Cardiovascular instability, hypotensive shock, and metabolic acidosis may persist. Therefore, the physician must understand that hypovolemia and decreased myocardial function may result from the asphyxial component of submersion injuries. The cardiogenic component may be related to hypoxic injury, dysrhythmia, or metabolic acidosis. In addition, pulmonary vascular resistance may be increased as a result of pulmonary vasoconstriction and the release of various inflammatory mediators. This increased resistance affects right-sided heart function and further decreases left-sided heart performance. This additive effect results in decreased left-sided filling pressures and a further decrease in oxygen delivery to an already compromised periphery, which further potentiates the metabolic acidosis seen with submersion injuries. If cardiovascular instability continues, then the physician must consider sepsis or further myocardial dysfunction.

### Effects on the Central Nervous System

Profound CNS dysfunction is the ultimate complication of submersion injuries. The duration of hypoxia and hypotension determines the severity of the neurologic injury seen after serious submersion events. As the neurons are deprived of oxygen, the patient loses consciousness. After this stage, blood flow to the CNS may be increased, resulting in a reperfusion injury, followed by a marked decrease in cerebral blood flow. Thus, the pediatrician may see severe CNS injury even after the restoration of cardiac output, normalization of blood pressure, and adequate oxygenation.

Given that intensive care unit techniques have advanced to improve cardiac output and innovations in mechanical ventilation have resulted in the restoration of a favorable acid–base status and oxygenation, the degree of CNS injury remains the major determinant of survival and neurologic morbidity in patients with asystole who are resuscitated and then transferred to a pediatric intensive care unit (PICU). The exact mechanism of CNS injury is complex and includes increased intracranial pressure, vasogenic changes in autoregulation and cytotoxic cerebral edema, and the accumulation of various metabolites and oxygen free radicals. Although hypothermia from the submersion injury may have some protective effects on the CNS, the child's outcome after submersion injuries will be determined within the first 24 to 72 hours.

### Multisystem Organ Effects

In addition to the pulmonary, hemodynamic, and CNS effects, other organ systems in the body may be adversely affected. These organ systems include the gastrointestinal system, the liver, kidney, and hematopoietic systems with disseminated intravascular coagulation. One of the other ominous signs is discharge from the rectum of material sloughed from the intestinal mucosa mixed with blood. This discharge is commonly associated with severe hypoxic-ischemic injury after the perfusion to the gastrointestinal tract becomes severely reduced, followed by gut necrosis. In addition, severe hypoxic-ischemic injuries may result in coagulopathy, renal failure, and predisposition to infection.

### Other Effects

Hypothermia is among the physiologic changes that occurs most commonly in association with submersion injuries. Children submerged in cold water (<41°F [5°C]) have had astonishing outcomes. The period of submersion hypothermia may protect the CNS. Severe hypothermia results in a decrease in energy use and thus decreases the metabolic rate of the brain. For each 1°C reduction in core temperature, the cerebral metabolic rate is reduced by 6% to 7%. Severe hypothermia may result in cardiac dysrhythmia, loss of consciousness, and a predisposition to infection.

During a submersion incident, the diving reflex may provide some form of protection. This well-known reflex, which is present in diving mammals such as seals, allows oxygen to be conserved. The diving reflex enables these animals to be submerged for 15 or 20 minutes. The reflex results in a marked reduction of blood flow to tissues that are more resistant to hypoxia while

preserving blood flow to more sensitive organs such as the brain and heart. However, the role of the diving reflex in submersion in children is uncertain.

In addition to hypothermia and the diving reflex, other preexisting associated conditions may be relevant in submersion injuries. Children with underlying seizure disorders, occult cardiomyopathy, or alterations in the myocardial conduction system may be predisposed to submersion injuries.

## APPROACH TO SUBMERSION INJURY

The approach to a child who has experienced significant submersion injury has been standardized and involves a minimum of 4 phases: initial lay person rescue at the scene, emergency medical team or paramedic response, stabilization in the ED, and care in the PICU.

### Initial Lay Person Rescue

The initial lay person rescue at the scene consists of identifying the problem and activating the local emergency medical services, removing the child from the water, and clearing the airway and performing CPR for a child who meets guidelines for initiating CPR until the emergency medical team arrives. Effective CPR at the scene is one of the major determinants of success in submersion injuries. The lay rescuer should note the time that CPR was initiated. If possible, an estimation of length of time of submersion should be noted, as should the temperature of the water.

### Emergency Medical Team or Paramedic Response

At the scene, determining the extent of the CNS injury is often initially difficult. Therefore, every effort is made to resuscitate the child to restore cardiac output, oxygenation, and acid–base status. The best approach is to ignore the down time that the child may have had during this initial resuscitative phase. Assessing the patency of the airway is critical, as is clearing the airway of any debris before attempting to ventilate the patient either with a bag-mask device or through intubation in the field. Efforts should be made to protect the airway from the aspiration of stomach contents and the lungs from aggressive positive pressure ventilation, which may produce overdistention of the lungs and possibly barotrauma.

Once a palpable pulse has been established and adequate chest wall rise is observed, the child should be transported to the closest ED that can deal with children. The child's vital signs, including temperature, should be assessed, and the child's cardiorespiratory status should be monitored, which includes continuous electrocardiographic monitoring, recording of oxygen saturation, and, if possible, intermittent recording of blood pressure. Most children in submersion incidents do *not* need spinal motion restriction. It is also important for the child to be dried and warmed.

### Stabilization in the Emergency Department

On arrival in the ED, for further stabilization and evaluation the child should be placed in a room large enough to provide space for the many interventions that will be required: a careful examination, which

includes a survey to ascertain whether any other traumatic injuries exist that are associated with the submersion event (eg, head injury, thoracoabdominal injury); further stabilization of the patient, which includes the use of equipment needed for vascular access, gastric decompression, and bladder catheterization; and provision of appropriate respiratory support. In addition, the child should be dried and warmed to a core temperature greater than 95°F (35°C).

For children who are spontaneously moving and breathing, close observation and monitoring are required to ensure that response to the submersion injury is not delayed. Children who are well saturated in room air and who have age-appropriate responses and a normal Glasgow coma score may be discharged after 4 to 8 hours; however, those with abnormal findings on chest radiograph, who require significant amounts of oxygen, or who have abnormal sensorium need to be admitted to the hospital. They may also require imaging studies while in the ED to make certain that the internal organs are not adversely affected (eg, CT scan of the head to rule out a concomitant CNS hemorrhage). It had been common practice that all patients be admitted for a period of observation for delayed onset of pulmonary edema. There seems to be a movement for short-term observation and discharge from the ED if the child has returned to his/her pre-submersion state, has no respiratory issues, and is neurologically intact.

Patients who were intubated in the field require thorough evaluation in the ED before being extubated. At most institutions, these children will probably remain intubated and mechanically ventilated. The patient then requires transfer to the closest PICU. The stomach must be decompressed with a nasogastric tube, a bladder catheter must be placed to measure urine output, and appropriate vascular access lines must be inserted. If the patient was not intubated in the field but now has poor oxygenation, displays signs that indicate increased work of breathing, or has a high oxygen requirement, then positive pressure ventilation is indicated. The child should then be intubated with an appropriately sized endotracheal tube. The patient should be placed on the appropriate ventilator setting for the underlying condition. Patients who are intubated and mechanically ventilated may need sedatives and paralytics to facilitate effective management. Obviously, if possible the neurologic status of the patient should be documented before the administration of paralytics.

To facilitate intubation, the physicians may administer a paralytic and an analgesic-amnesic agent. The patient's neurologic status is continuously monitored and documented before transfer to the PICU. In addition, if indicated, the physician may wish to order a CT scan to evaluate the brain and to determine whether an associated traumatic head injury has occurred. The spine should also be evaluated and cleared. In those who have an altered mental status it may not be possible to clear the spine and thus precautions to protect the spine must be continued in the PICU. All lines and tubes must be stabilized to make certain that the patient cannot dislodge any of the lines or the endotracheal tube.

Efforts should be made to restore vascular volume with an isotonic solution (10–20 mL/kg). The patient should be warmed to treat existing hypothermia and prevent further hypothermia, which can be associated with abnormal cardiac rhythms. Antibiotic treatment may be initiated if the patient aspirated contaminated water or if pulmonary infection is suspected. Before transfer to the PICU, radiographic studies must be performed to confirm the placement of the endotracheal tube, vascular access catheters, and contour of the lungs. Patients should also be assessed to ensure that no pneumothorax or other evidence of air leak exists.

### Care in the Pediatric Intensive Care Unit

On the child's arrival into the PICU, the physician closely monitors all vital signs, including oxygen saturation, end-tidal carbon dioxide (either inline with the ventilator, or with a nasal cannula-based capnometry device).

All PICU efforts are aimed at minimizing any injury that resulted from the submersion event itself, because the primary injury—the hypoxic-ischemic event—cannot currently be treated. PICU efforts are now directed to supportive care of the patient and trying to minimize secondary or further neurologic injury.

If the patient is intubated, an arterial line should be placed, and if the child requires cardiovascular support with inotropes, then a central venous catheter should be placed. Further management is aimed at restoring cardiac output, minimizing injury to the brain, and preventing catastrophic complications. Neurointensive care support is often required; however, aggressive management of intracranial hypertension with osmotic agents, hypothermia, hyperventilation, steroids, or barbiturate-induced coma has not proved to be of much benefit. In fact, these interventions may increase the risk for nosocomial infections, pulmonary insufficiency, and cardiac dysfunction.

The approach taken in the PICU varies from institution to institution, but the major goal is always to restore the child, if possible, to the previous state of health by preventing further injury to the brain. Efforts should be made to assess the degree of neurologic injury over the first 24 to 48 hours. Electroencephalographic monitoring may help with the recognition of electrical seizures. Seizure activity should be treated quickly and aggressively. Monitoring intracranial pressure has not proved to be of benefit for these patients. Patients should only receive sedation if it is clinically indicated. The severity of the encephalopathy is the main determinant of outcome.

When possible, nutritional support is provided either in the form of enteral nutrition if the intestinal tract can tolerate feeds or parenteral nutrition once the patient's fluid and electrolytes issues have resolved. Normalization of blood gases by various ventilatory strategies (to ensure adequate oxygenation and acid-base status) is preferred to hyperventilation. The appropriate support of the cardiovascular system with inotropes as needed to maintain an adequate blood pressure is required to maintain blood flow to vital organs. Minimizing the development of stress ulcers in the gastric mucosa is vitally important;

thus, agents may be used to maintain a gastric pH of greater than 5. This can be accomplished with either proton pump inhibitors or H<sub>2</sub> blockers. The appropriate use of antibiotics to treat suspected or proven infections is often necessary, because submersion victims are susceptible to bacterial infections that result from aspiration of water. Bacterial infections also may result from complications of mechanical ventilation or vascular access attempts. Therefore, initiating empiric antibiotic treatment may be reasonable.

A periodic review of blood tests for changes in hematocrit level, coagulation profile, or white blood cell count is also important. A review of liver and renal function studies helps the pediatrician ascertain whether other organs have been injured. Unusual forms of ventilatory support may include the use of high-frequency ventilation for acute pulmonary injury, inhaled nitric oxide for severe hypoxia-induced respiratory failure, and extracorporeal oxygenation. Extracorporeal oxygenation, which may be used for rewarming, theoretically allows the lungs to rest, helping to prevent barotraumas associated with high airway pressures.

### When Neurologic Function Is Likely to Be Impaired

When a child has experienced a serious submersion injury and remains comatose 72 hours after the incident despite interventions, the child will not likely recover full neurologic function. This fact must be explained to the child's parents within 12 to 24 hours after the child's admission to the PICU. A multidisciplinary meeting (neurologists, primary care physician, PICU nurses, and a social worker assigned to the case) should be held with the family to explain in great detail the potential outcomes of children who have experienced a serious submersion injury and who are still comatose. Palliative care may be incorporated in the care plan, as palliative care skill sets may be very helpful for the pediatricians in the ICU, staff, and the family. Clearly, once it has been determined that severe neurologic sequelae have occurred, the family needs to be made aware of the various options now available for the ongoing care of the child. It may be helpful for the families to understand what long-term care needs may require, such as tracheostomy, gastrostomy and possibly placement in a subacute care facility if one exists. Families should also be informed that appropriate care may not require such interventions, and that natural death can be allowed to occur by limiting further interventions and providing more comfort care measures.

At this initial meeting, depending on the child's clinical condition, the full spectrum of outcomes should be presented in an open and forthright manner: the child may regain much, but not all, of previous neurologic function; the child may experience less severe neurologic sequelae; or the child may remain in a vegetative state or experience brain death.

During the next 48 to 72 hours, if the patient does not return to appropriate neurologic functioning, then the family is presented with this information again so that the difficult process of deciding what to do next

can begin. The parents need to make informed decisions about aggressive approaches to care. Once the determination has been made that the child's chances for meaningful survival are remote, the family may be presented with information about the potential need for technology-based ongoing support; long-term mechanical ventilation, tracheostomy, gastrostomy feeds, and fundoplication. In addition, the parents may consider placing the child in a long-term or chronic care facility or nursing the child at home. It may be beneficial for the family to visit a long-term care facility before making decisions regarding further life-prolonging interventions.

A pediatric palliative care consultation helps the parents make these complex decisions. Family members must participate in decisions about further aggressive care or decisions to limit or withdraw care based on the potential for poor outcome. This participation empowers the parents to decide to limit aggressive interventions that will not change the ultimate outcome. A natural death may result from withdrawing life support. If the parents choose this route, they must be prepared to deal with an extubation that results in the child's death. In such instances, if possible, a *do-not-resuscitate* order should be obtained.

Some parents may wish to attempt extubation with the idea that if the child does not succeed with breathing without mechanical ventilation, then the child will be reintubated, thereby providing the parents with more time to come to a consensus about what to do next. Nonetheless, once the medical team has established that the most likely neurologic outcome for the child is the potential for severe encephalopathy or a persistent vegetative state, some parents request that the child be extubated, not reintubated, and permitted to die naturally. A *do-not-resuscitate* order on record ensures that no further heroic efforts will be undertaken to save the child.

An open, honest policy enables parents to participate in decisions that will profoundly affect them for years to come. The health care team should provide resources to the family as needed: support for sustaining the child in a long-term care facility should be provided to the family, or after a child's death, the palliative care team or another specialist may provide bereavement support for the family. (See Chapter 67, Palliative, End-of-Life, and Bereavement Care.)

## PREVENTION

The overall effect of submersion injury prevention and pool safety cannot be overstated. The efforts of the American Academy of Pediatrics and communities have resulted in a reduction in serious submersion injuries by advocating standards for pool safety. During routine office visits, primary care physicians need to educate families about pool safety.

A swimming pool in the yard can be dangerous for children. If possible, swimming pools should not be built until the children in the household are older than 5 years. If a pool is already in place, then safety measures should be undertaken to prevent drowning. Box 356-1 provides tips on how to protect children from drowning.

### BOX 356-1 How to Protect Children From Drowning

- Never leave your children alone in or near the pool, even for a moment.
- Put up a fence to separate your house from the pool. Most young children who drown in pools wander out of the house and fall into the pool. Install a fence at least 4 feet high around all 4 sides of the pool. This fence will completely separate the pool from the house and play area of the yard. Use gates that auto-close and auto-latch, with latches higher than your children's reach.
- Consider the use of a safety cover. A power safety cover that meets the standards of the American Society for Testing and Materials adds to the protection of your children but should not be used in place of the fence between your house and the pool. Even fencing around your pool and using a power safety cover will not prevent all drownings.
- Keep rescue equipment (eg, a shepherd's hook, life preserver) and a telephone by the pool.
- Do not let your child use air-filled swimming aids because they are not a substitute for approved life vests and can be dangerous.
- Know CPR. Anyone watching young children around a pool should learn CPR and be able to rescue a child if needed. Stay within an arm's length of your child.
- Remove all toys from the pool after use so children are not tempted to reach for them.
- After the children are finished swimming, secure the pool so they cannot get back into it.
- Teaching your child how to swim does not mean that your child is safe in water.

## Chapter 357 DRUG OVERDOSE

Angela Lumba-Brown, MD

### FOUNDATION

#### Definition

*Pediatric drug overdose* refers to the intentional or accidental ingestion of a drug not medically recommended or the intentional or accidental ingestion of a drug in quantities larger than medically recommended for that child.

#### Epidemiology

Pediatric drug overdose is a serious public health problem that can have fatal consequences. Calls to the Poison Control Center about medication ingestion in children increased by 10% from 2002 to 2006. More than 70,000 children younger than 18 years are treated for accidental or intentional drug overdoses in US emergency departments (EDs) annually. Eighty-one percent of ED visits for drug overdose involve children younger than 6 years. Fatalities in this age group are most often caused by overdose of analgesics, followed by antihistamines, and then sedative-hypnotic-antipsychotic drugs. At all ages, analgesics are the most common pediatric poisoning in general (68%), surpassing poisoning from household product ingestion.

#### Etiology

Pediatric drug overdose can be separated into 2 categories—intentional and accidental. Intentional overdoses occur when the patient ingests medications

with the intent to self-harm, for recreational drug misuse, or as a symptom of a substance use disorder.

Misuse, defined as the nonmedical use of a drug, is the main cause of medication overdose in children aged 13 to 19 years. The 2011 National Survey on Drug Use and Health reported that 2.8% of 12- to 17-year-olds reported nonmedical use of prescription drugs within the past month.

Accidental drug overdoses occur as a result of therapeutic errors or inadvertent ingestion. The Poison Prevention Packaging Act of 1970 mandated child-resistant packaging for hazardous products and prescription drugs. Subsequently, the Consumer Product Safety Commission reported a reduction of 1.4 deaths per 1 million children younger than 5 years. Despite this improvement, children younger than 5 years continue to have the highest incidence of accidental drug overdose.

Fourteen percent of ED visits occur because of medication errors and misuse. Most ED presentations for pediatric drug overdose (82.2%) occur as a result of unsupervised ingestions.

### Risk Factors

The risk factors for pediatric drug overdose are multifactorial.

In the United States, 82% of adults and 56% of children take at least 1 medication at home. Frequency of use and storage of medications at home increase the

potential for drug overdose. Further risk factors are discussed in Box 357-1.

## DIAGNOSIS

### Signs and Symptoms

Manifestations of overdose may affect any organ system and are related to the type of drug ingested. Identifying signs and symptoms representative of a specific toxidrome aids in the diagnosis of drug overdose, especially if the ingestion was unwitnessed.

Common general overdose symptoms include nausea and vomiting, abdominal pain, diarrhea, skin flushing, diaphoresis, abnormal respiratory patterns, temperature abnormalities, visual disturbances, pupil irregularities, paresthesia, agitation, lethargy, irritability, and altered mental status.

Complications of drug overdose include seizures, further mental status changes, hemodynamic instability, hypoglycemia, cardiac arrhythmia, and death.

### Differential Diagnosis

The differential diagnosis of drug overdose is broad; see Box 357-2.

### Diagnostic Approach

Diagnostic approach to the pediatric patient with a possible drug overdose begins with the rapid identification of the critically ill patient by assessing the airway, breathing, circulation, and disability. Full vital signs, including blood pressure, are obtained as soon as possible in a child with a possible drug overdose to aid in determining respiratory and hemodynamic compromise. A complete physical examination follows and can be concurrent with history taking. Patients with drug overdose may have pupillary abnormalities or other abnormal eye movements; abnormal odors that

### BOX 357-1 Risk Factors for Pediatric Drug Overdose

- **Age:** Toddlers and young children may ingest medications in play or with the assumption of a drug being food or candy.<sup>a</sup> Adolescents may purposefully ingest drugs for recreational or self-harm purposes.
- **Availability:** Child-resistant packaging has made accidental pediatric drug overdose more technically challenging. However, the presence of medications in the household and within a child's reach is a risk factor for ingestion.
- **Decreased or inadequate supervision:** Unintentional ingestions in young children often occur when they are unsupervised.<sup>b</sup>
- **Unclear medication dosage or directions:** Often, children's medications are liquid formulations requiring measurement and administration by parents, allowing for medication error.
- **Previous self-harm attempt:** Teens and adolescents who have previously attempted drug ingestion as a suicidal attempt or gesture are at risk for repeat attempt.<sup>c</sup>
- **Drug abuse:** Teens and adolescents who abuse drugs are at risk for drug overdose.

<sup>b</sup>Bryant S, Singer J. Management of toxic exposure in children. *Emerg Med Clin North Am.* 2003;21(1):101-119.

<sup>c</sup>Reid WH. Prognosis after suicide attempt: standard of care and the consequences of not meeting it. *J Psychiatr Pract.* 2009;15(2):141-144.

### BOX 357-2 Differential Diagnosis of Drug Overdose

- Meningitis and encephalitis
- Seizure
- Metabolic derangements like hypothermia and hyponatremia
- Diabetes with hypoglycemia and hyperglycemia
- Endocrinologic emergencies, such as thyroid and adrenal dysfunction
- Trauma
- Pneumonia
- Cardiac arrhythmia
- Sepsis
- Gastroenteritis
- Envenomation
- Dehydration
- Other poisonings
- Psychiatric conditions

are characteristic of a specific ingestion, such as the smell of wintergreen in a patient who has a salicylate overdose; neurologic abnormalities, such as change in tone or clonus; and skin changes, such as absent perspiration or flushing. The physical examination also includes an evaluation of mental status and current cognition to assess for altered mental status, lethargy, and cognitive derangements. The physician should place the patient in a position of comfort with the airway maximized; be ready to perform cardiopulmonary resuscitation if necessary; and obtain the patient's weight, height, and age.

The history of ingestion begins with the patient and caregiver interview to determine the name, quantity, and dosage of the medication ingested. (See Figure 357-1). If the amount is unknown, the physician can count the number of pills or tablets in the bottle and determine how many were originally in the bottle, if it is available. If the drug ingestion is unknown, caregivers can provide information

regarding medications in the home and medications potentially brought into the home by visitors.

Past medical history, including history of recent illness, may contribute to the clinical picture of the patient with an overdose and raise concern for compounded symptoms. For example, a beta-blocker overdose in an asthmatic patient may have more serious consequences. Other important points in the patient's history include recent medication use and chronic medication use that may represent an overdose or that may affect metabolism of the overdose. The patient's last oral intake and allergies may change management planning.

Physicians must identify the circumstances of exposure and intent and discuss any previous history of self-harm, suicide attempts, or drug use. If the ingestion is a suspected or confirmed attempt for self-harm or suicide, the patient will require constant observation.

Patients who present within the first hour of ingesting a life-threatening amount of a known or suspected

**Table 357-1** Lethal Pediatric Drug Overdoses: “One Pill Can Kill”

DRUG	MANIFESTATIONS	MANAGEMENT CONSIDERATIONS
Beta blockers	Hypotension	Glucagon Fluid resuscitation Vasopressors
Calcium channel blockers	Hypotension	Calcium replacement Insulin and glucose Fluid resuscitation Vasopressors
Camphor	Central nervous system excitation/ seizures Respiratory depression	Airway control Activated charcoal Benzodiazepines for seizures
Quinine derivatives, including cardiac glycosides and antimalarials	Cardiac dysrhythmia and prolonged QRS duration and/or prolonged QT interval Neurotoxicity and seizures Cinchonism Hypokalemia	Sodium bicarbonate Potassium replacement
Clonidine Oxymetazoline	Bradycardia Hypotension Respiratory depression Miosis	Atropine Consider naloxone Supportive care Vasopressors
Opioids/narcotics	Central nervous system depression Respiratory failure	Naloxone; likely to need repeat doses or continuous infusion resulting from short half-life
Oral hypoglycemic (eg, sulfonylureas)	Hypoglycemia	Glucose Glucagon Inpatient monitoring
Salicylates	Metabolic derangement	Activated charcoal Sodium bicarbonate Possible hemodialysis
Tricyclic antidepressants (eg, imipramine, desipramine, amitriptyline)	Cardiac dysrhythmia with QRS widening Anticholinergic symptoms Hypotension	Airway control Activated charcoal Benzodiazepines for seizures Cardiac monitoring

drug may require immediate administration of activated charcoal. See Table 357-1 for a list of drugs that can be lethal in children.

### Laboratory Findings

The laboratory evaluation of a child with a suspected drug overdose includes the tests listed in Table 357-2. Many drugs can cause cardiac arrhythmias, such as widened QRS or prolonged QT intervals. The physician should obtain a 12-lead electrocardiogram in cases of such drugs and in cases of hemodynamic instability.

### Imaging

Abdominal radiographs may identify radiopaque medications, such as chloral hydrate, iron-containing preparations, calcium carbonate, iodinated compounds, acetazolamide, busulfan, and potassium preparations. Antihistamines, phenothiazines, and tricyclic antidepressants exhibit varying radiopacity. Factors like the size of the patient, concentration of enteric

coating of the pill, air density, and layering in the gastrointestinal tract affect visibility on plain radiograph.

In the obtunded patient, head computed tomography can rule out other causes of altered mental status.

A chest radiograph should be obtained if there is concern for aspiration of the drug or aspiration pneumonia. A chest radiograph may also be obtained to confirm the placement of nasogastric tubes, central lines, and endotracheal tubes.

## MANAGEMENT

### Treatment Approach

The caregiver of a child with suspected toxic ingestion should immediately consult with the local Poison Control Center at 800-222-1222.

The obtunded or hemodynamically unstable patient requires immediate intravenous (IV) access and application of supplemental oxygen via non-rebreather face mask. The physician should begin fluid resuscitation in hemodynamically unstable patients with 20 mL/kg of

**Table 357-2** Laboratory Evaluation of a Child With Suspected Drug Overdose

TEST	FACILITY	PURPOSE
Serum glucose	Rapid Bedside	Hypoglycemia may be caused by many drug ingestions, such as oral hypoglycemic agents, beta blockers, insulin, salicylates, and quinine Hyperglycemia may be caused by beta agonists and calcium channel blockers
Urine pregnancy	Within 1 hr	Qualitative identification of pregnancy in an adolescent
Urine drug screen	Within 6 hr	Qualitative standard testing of amphetamine, barbiturates, benzodiazepines, cocaine, marijuana, opiates, phencyclidine May be useful in children in whom diagnosis is uncertain
Venous blood gas	Within 30 min	Assesses acid-base status and ventilation Increased anion gap metabolic acidosis suggests salicylate, ethylene glycol, and methanol overdose
Basic metabolic panel	Within 1 hr	Reports electrolyte levels and evaluate for renal function Allows calculation of anion gap ( $\text{Na} - [\text{Cl} + \text{HCO}_3]$ ) Hyperkalemia may occur with overdose of cardiac glycosides Hypokalemia may occur with overdose of beta agonists
Urinalysis	Within 6 hr	Assesses specific gravity and presence of myoglobin to suggest rhabdomyolysis Calcium oxalate crystals may suggest ethylene glycol ingestion
Ethanol breathalyzer	Rapid	Allows for rapid assessment of the breath alcohol content
Serum ethanol level	Within 6 hr	Quantitative evaluation of blood alcohol content
Osmolar gap	Within 6 hr	Elevated osmolar gap may occur in alcohol poisonings
Quantitative serum acetaminophen	Within 6 hr	Assesses for toxic levels Should be screened for in any intentional poisonings
Quantitative serum salicylate	Within 6 hr	Assesses for toxic levels Should be screened for in any intentional poisonings
Liver function tests	Within 1 hr	Evaluation of baseline status if acetaminophen ingestion is suspected
Coagulation panel	Within 6 hr	Evaluation of baseline status in acetaminophen and salicylate ingestions

crystalloid fluid and obtain a bedside blood glucose measurement. The physician should consider naloxone administration empirically in the patient with miosis and altered mental status if other causes are not apparent. Children suspected of having a drug overdose who are actively seizing should be treated with benzodiazepines while other reasons for seizure, such as hypoglycemia, hyponatremia, or isoniazid ingestion, are evaluated. Immediate endotracheal intubation is required in the obtunded patient who is unable to maintain her airway, displays ineffective oxygenation, lacks a gag reflex, or declines rapidly.

### Activated Charcoal

Activated charcoal should not be used in the home, but it has a role in decontamination following life-threatening, acute pediatric drug overdose in the ED setting. Activated charcoal reduces drug absorption and enhances elimination. It may be effective if given within 1 hour of ingestion at a dose of 1 g/kg up to

50 g per dose, although it can be beneficial up to 4 hours after ingestion. Complications of activated charcoal administration, especially multi-dose activated charcoal or charcoal-cathartic combinations, are nausea, vomiting, aspiration, possible pulmonary aspiration, constipation, hypovolemia, hypernatremia, and hypermagnesemia. Multiple doses of activated charcoal should be considered after life-threatening ingestions of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Some slow-release medications, metals, and electrolytes are not bound by activated charcoal.

Cathartics alone have no role in the management of the drug-overdosed patient, and they should not be used with multidose administration of activated charcoal.

### Sodium Polystyrene Sulfonate

Sodium polystyrene sulfonate is a salt that acts as a cation binder. It is an effective therapy in lithium

overdoses and for hyperkalemia. Complications are hypokalemia and constipation.

### **Whole Bowel Irrigation**

Whole bowel irrigation is used to increase the gastrointestinal transit time of a drug and thereby decrease its absorption and in cases of life-threatening ingestion of select agents in the acute setting—this occurs generally within the first 60 minutes. Whole bowel irrigation may be useful in life-threatening ingestions of sustained-release preparations, enteric-coated pills, and very large ingestions including drug packets. A polyethylene glycol electrolyte solution is administered at a rate of 500 mL/hour in children aged 9 months to 6 years, 1,000 mL/hour in children aged 6 to 12 years, and 1,500 to 2,000 mL/hour in adolescents and adults, often by nasogastric tube. Whole bowel irrigation used after administration of activated charcoal decreases its efficacy of binding. Use is contraindicated in the child with an unstable airway or hemodynamic status, active seizures, or concern for bowel obstruction.

### **Syrup of Ipecac**

Home use of syrup of ipecac in ingestions has not been shown to improve patient outcome or reduce resource use. The American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists do not recommend its use in the ED.

### **Gastric Lavage**

Studies have not shown a benefit of gastric lavage compared with activated charcoal administration. There are potential adverse effects of gastric lavage, such as gastrointestinal perforation, pulmonary aspiration, and pneumonia. Additionally, pediatric-sized gastric tubes may not be large enough to remove pills.

### **Supportive Care**

For the most part, management of pediatric drug overdose is exclusively supportive. Patients in respiratory distress should be placed on oxygen via a non-rebreather face mask to titrate oxygen saturations to greater than 93%. Patients with altered mental status or without gag reflex should be intubated and ventilated. A trial of naloxone (0.1 mg/kg IV) may be helpful in these patients.

Hypotension should be treated with bolus infusions of crystalloid fluid. For refractory hypotension, vasopressors, such as norepinephrine, should be initiated. Bradyarrhythmias should be treated with atropine.

Conversely, hypertension may be a manifestation of overdose. In this case, if hypertension is suspected to be because of agitation, benzodiazepines may be employed. In hypertensive crisis, phentolamine or nitroprusside may be used. The exclusive administration of beta blockers should not be used because of the risk for subsequent alpha blockade and worsening clinical status.

Physicians should immediately evaluate for hypoglycemia and treat with oral or IV dextrose, if indicated. The starting glucose dosage is 2.5 mL/kg of dextrose 10% via peripheral IV. If the patient cannot

tolerate oral medication and IV access is not readily available, subcutaneous glucagon may be administered at 0.03 mg/kg up to a maximum of 1 mg.

### **Specific Antidotes**

Several drugs have known antidotes and are listed in Table 357-3.

## **ONGOING CARE**

### **Follow-up**

In patients without symptoms, 6 hours of ED observation for signs of drug overdose, such as hypotension, cardiac arrhythmia, or seizures, is generally sufficient in most cases of suspected pediatric drug ingestion. However, if an extended-release medication is a suspected ingestant, such as a hypoglycemic agent, the patient should be admitted for monitoring overnight. Additionally, it is important to note that a drug's calculated half-life is based on therapeutic dosing and cannot be readily applied in the scenario of overdose.

All patients who intentionally overdose for either recreational purposes or in suicide attempt require evaluation by a trained social worker. Those with suicidal intent also require psychiatric assessment and inpatient admission until deemed psychiatrically stable.

If a caregiver is suspected to have intentionally given a drug to the child or caused the child's overdose, or if inadequate supervision is suspected, Child Protective Services must be notified. All states have laws mandating that physicians and other medical personnel report suspected child abuse and neglect.

### **Complications**

The complications of pediatric drug overdose depend on the medication ingested. Prolonged hypoglycemia caused by ingestion of oral hypoglycemic agents or resulting from induced metabolic derangements can cause brain injury, coma, and death. Hypoxemia caused by the depressed respiratory drive in opioid- or clonidine-overdosed patients can cause brain injury and death. Overdoses causing prolonged seizures like antihistamines, cyclic antidepressants, or isoniazid may result in rhabdomyolysis and renal dysfunction or failure. Acetaminophen poisoning can cause hepatitis and liver failure.

### **Prognosis**

Three-fourths of calls to the Poison Control Center are managed over the telephone and do not result in direct treatment by a health care professional. Most children with drug overdose return to their baseline health status within 24 hours.

In 2010, only 11% to 12% of children younger than 13 years who were reported to the Poison Control Center for toxic ingestion were admitted to the hospital. Meanwhile, 48% of teens aged 13 to 19 years reported for toxic ingestion were admitted for hospital management. There are 4 times as many hospital admissions for teens as for young children because most teen overdoses are intentional.

In 2010, there were 91 pediatric fatalities due to toxic ingestion reported by the American Association of Poison Control Centers National Poison Data System. Forty-six of these fatalities were in 13- to 19-year-old

**Table 357-3** Drug Ingestions and Their Specific Antidotes

DRUG	TREATMENT	DOSAGE
Acetaminophen	N-acetylcysteine	Oral: 140 mg/kg/dose PO, then 70 mg/kg/dose every 4 hr PO x 17 doses. IV: 150 mg/kg IV over 1 hr, then 50 mg/kg over 4 hr, then 100 mg/kg IV over 16 hr.
Anticholinergics	Physostigmine	0.02 mg/kg IV infusion to be administered no faster than 0.5 mg/min, to repeat every 10 min as needed with a maximum total dose of 2 mg. Not for use in patients with widened QRS.
Beta blockers	Glucagon	0.15 mg/kg initially over 1 min followed by repeat dose, if necessary, and continuous infusion at 0.1 mg/kg/hr.
Benzodiazepines	Flumazenil	0.01 mg/kg IV every 1 min for 1–5 doses (maximum dose, 0.2 mg/dose).
Calcium channel blockers	Calcium Insulin	Calcium gluconate: 100 mg/kg IV. Calcium chloride via central venous line: 20 mg/kg IV. Repeat doses as needed. Insulin: 1 U/kg IV with a glucose infusion.
Cardiac glycosides	Digoxin-specific antibody (Fab) fragments Atropine, in symptomatic bradycardia	Digibind: 5–10 vials via slow IV push for children. Atropine: 0.02 mg/kg IV.
Ethylene glycol and methanol	Ethanol Fomepizole	Loading dose: 10 mg/kg IV or PO, followed by maintenance dose 1 to 2 mL/kg/hr IV or PO. 15 mg/kg IV bolus, then 10 mg/kg IV every 12 hr for 4 doses; after these, increase dose back to 15 mg/kg.
Iron	Deferoxamine	15 mg/kg/hr IV for 8 hr.
Narcotics/opioids	Naloxone	0.1 mg/kg IV (maximum, 2 mg) per dose, may be repeated every 3 min for effect, with a maximum cumulative dose of 10 mg.
Oral hypoglycemic agents	Glucose Glucagon Octreotide	2.5–5 mL/kg dextrose 10% IV. 2–4 mL/kg dextrose 25% IV. 1–2 mL/kg dextrose 50% IV via central line. 0.03 mg/kg up to a maximum of 1 mg. Consult Poison Control Center.
Tricyclic antidepressants (eg, imipramine, desipramine, amitriptyline)	Sodium bicarbonate	1–2 mEq/kg IV bolus for widened QRS; may repeat to maintain effect.

IV, intravenous; PO, by mouth.

children with intentional exposures. Twenty-six fatalities occurred in children 5 years of age and younger.

### Prevention

Strategies to prevent pediatric drug overdose are categorized as engineering, educational, and enforcing.

- *Engineering* involves modifying the drug or how it is accessed. The Poison Prevention Packaging Act of 1970 mandated childproof containers on all

prescription medications, resulting in an estimated reduction in the child mortality rate from accidental drug overdose by 45% between 1974 and 1992.

- *Education* of caregivers by their pediatricians and dispensing pharmacists regarding the dangers of drug overdose may modify behaviors of medication storage and therapeutic errors. Adolescent and teen counseling by parents, pediatricians, school health counselors, public service announcements,

and outreach programs may help to prevent drug misuse and overdose. Pediatric patients who have intentionally overdosed on a medication require psychiatric assessment.

- **Enforcement** refers to upholding drug dosing, packaging, and administration regulations. Therapeutic errors by health care workers may be enforced by hospital policy and legal measures.

### WHEN TO REFER

To a Poison Control Center or toxicologist

- Ingestion of any known or unidentified drug
- Suspicion of a toxic ingestion

To the emergency department

- Suspicion of a toxic ingestion
- Concern for potential decompensation
- Monitored observation required
- Acute ingestion that would benefit from activated charcoal administration or whole bowel irrigation
- Hemodynamic instability
- Altered mental status
- Concern for child abuse or intent for self-harm/suicidal intent

### WHEN TO ADMIT

- Concern for potential decompensation
- Prolonged monitored observation required
- Worsening medical status
- Hemodynamic instability
- Hypoxemia
- Hypoglycemia
- Significant metabolic acidosis or electrolyte derangement
- Protracted vomiting
- Cardiac dysrhythmia
- Altered mental status
- Respiratory distress
- Inability to tolerate oral intake
- Concern for self-harm/suicidal intent

## Chapter 358 ENVENOMATIONS

Shireen Banerji, PharmD; Alvin C. Bronstein, MD

Envenomations present unique problems in children. An amount of venom injected that may not be enough to cause morbidity in an adult may be disastrous for a child. Venoms are complex chemical mixtures designed for either defending or hunting. Animal venoms used for immobilizing prey may also have predigestive effects to aid the hunter.

Various venom delivery systems exist. Most systems of clinical relevance consist of specially evolved exocrine gland mechanisms to make and store venom and a sophisticated delivery apparatus. Snake fangs resemble hypodermic needles, and the Hymenoptera stinging device is similar to a blood sampling stylet. *Envenomation* is the injection of venom through the bite or sting of venomous creatures. *Bites* refer to the injection through structures associated with the mouth and are primarily evolved for handling prey, whereas *stings* are delivered through a posterior structure (stinger) and are primarily defensive. Pediatricians, primary care physicians, and emergency medicine physicians often manage patients with complaints of envenomation. Concerns about allergic reactions, mostly from insects, result in referrals to allergy and immunology specialists. See Box 350-3 in Chapter 350, Anaphylaxis, for drugs and dosages for the management of anaphylaxis.

### EPIDEMIOLOGIC FEATURES

In 2013, the American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) reported 2,188,013 human exposures, with 56,378 resulting from bites or stings (see Table 358-1 for a partial breakdown). Of the 1,218 deaths reported, 4 (0.33%) were from bites and stings, and 1 involved a child younger than 6 years. Although bites and envenomations ranked number 14 of the top 25 substance categories most frequently involved in human exposures for all age groups reported in NPDS, they did not make the top 25 in children younger than 6 years.

**Table 358-1** National Poison Data System: 2013 Envenomation Exposures in the United States

ANIMAL	TOTAL	CHILDREN AGES 0–5 YEARS
Ants, fire ants	1,014	311
Hymenoptera	5,248	862
Scorpions	18,270	1,670
Total snakes	6,425	339
Crotalines	3,877	167
Coral	73	1
Total spiders	8,664	853
Brown recluse spiders	1,326	95
Black widow spiders	1,866	152

Excerpted from Mowry JB, Spyker DA, Cantilena LR, et al. 2013 Annual Report of the American Association of Poison Control Centers' National Poisoning Data System (NPDS): 31st Annual Report. *Clin Toxicol*. 2014;52:1032–1283.

Although most cases are minor, serious local and systemic injury can result. Consequently, the primary care physician must be aware of local venomous species and be able to recognize and treat the injuries caused by them. In North America, venomous species include arthropods, specifically Hymenoptera (bees, wasps, hornets, and ants), arachnids (spiders and scorpions), and snakes (pit vipers and coral snakes).

## HYMENOPTERA

In the United States, Hymenoptera are the largest order of insects known and are responsible for most insect stings. Hymenoptera include the family Apidae (honeybees), family Bombidae (bumblebees), superfamily Vespidae, and superfamily Formicidae (harvester ants and native and imported fire ants). Vespids consist of *Vespula* species (yellow jackets) and *Polistes fuscatus* (hornets and wasps). All Hymenoptera possess a posterior stinger.

Hymenoptera stings can cause local or systemic reactions. Reactions may be a direct effect of the venom, or they may occur through an IgE-mediated allergic reaction. Anaphylaxis from various origins results in approximately 400,000 visits to emergency departments annually. Hypersensitivity has been reported to occur in 0.05% to 5% of the population. This prevalence is second only to drug-induced (penicillin) anaphylaxis.

Large local cutaneous reactions to stings occur in approximately 2.3% to 18.6% of the general population. A history of systemic allergic reactions documented in medical records occurs in 0.8% of children. Biphasic anaphylactic reactions, characterized by return of symptoms 1 to 10 hours after the initial symptom resolution, may occur in up to 20% of patients. There are reports of returning symptoms being delayed up to 72 hours. Systemic allergic sequelae can occur at any age, often after numerous uncomplicated stings. Though evidence suggests that most children do outgrow systemic allergic responses to insect

stings, 1 in 5 individuals stung up to 32 years after the original reaction still elicit an allergic reaction. Death by honeybee or wasp envenomation is rare. In the United States, 40 to 100 people suffer fatal envenomation caused by bee, wasp, or ant stings annually. IgE-mediated type-1 anaphylaxis, although uncommon, is usually responsible for related deaths. Massive envenomations involving hundreds of stings may also result in death.

## Winged Hymenoptera

### Characteristics and Distribution

Winged Hymenoptera are found in most areas of the United States. Honeybees usually nest in hollow trees and crevices, whereas bumblebees prefer nesting underground. Wasp nests can often be found under roofs and eaves, hornets prefer to nest in the branches of trees, and yellow jackets tend to build their nests in the ground.

Most social bees and wasps sting primarily in defense of their nest or while in search of food. Yellow jacket wasps are common near exposed food and garbage, resulting in stings not associated with nest protection. Yellow jackets have also been implicated in frequent stings in late summer and early fall associated with *yellow jacket delirium*, a poorly understood seasonal behavior characterized by aggressiveness toward objects that are not threatening or provocative. If disturbed, any wasp or bee will sting in self-defense. Mass envenomations occur when a human is perceived to be intruding or threatening the colony. Honeybee colonies consist of approximately 40,000 workers, with Africanized honeybees having slightly smaller colonies. In contrast, yellow jackets and hornets maintain colonies of several hundred to a few thousand insects.

The sting apparatus, or *aculeus*, of wasps (vespids) and honeybees resembles a stylet with 2 shafts. The shafts, propelled by muscular attachments, alternately slide back and forth, like a saw, pulling the sting deep into the flesh. Barbs located in the tips of the stylet help anchor the aculeus. Venom is then pumped down a central channel into the wound. Unlike the aculeus of the honeybee, the vespids sting stylet is wider than the stylet shaft barbs, and the dorsal stylet surface is smooth, decreasing the likelihood that the sting will remain in the victim. The insect with the barbed stinger dies within hours to days after stinging because the stinger remains anchored in the skin of the victim, thereby eviscerating the insect. However, because vespids can withdraw their stingers, they are able to sting multiple times. When the stinging apparatus detaches from the insect and remains in the victim's skin, the muscles surrounding the venom sac contract and can pump venom into the flesh for an additional 30 to 60 seconds.

Much attention has been garnered by Africanized honeybees, commonly referred to as *killer bees*, which are now found in southern Texas, Arizona, and California. The original colonies of these bees were imported to South America to breed with European varieties in an attempt to increase honey production. However, the ensuing generations of bees retained the ferocity of the African bees. The bees are not more

individually dangerous than European bees. Their venom is similarly potent, and similar amounts are delivered per sting. However, their aggressive “swarm-and-attack” nature can result in massive envenomation because of the sheer number of stings delivered in an attack.

Venoms of the winged Hymenoptera contain many protein components that account for the reactions that have been observed. Phospholipids A<sub>2</sub>, hyaluronidase, histamine, apamin, melittin, mast cell degranulating peptide, acid phosphatase, norepinephrine, dopamine, and allergen C are the main constituents of honeybee venom. Mast cell degranulating protein causes cell breakdown and histamine release. Bumblebee venom contains acid phosphatase, tryptic amidase, and melittin. Melittin is the main pain-inducing compound, and it causes membrane integrity alteration. The major vespid allergens are antigen 5 and hyaluronidase, but they also contain histamine, kinins, serotonin, phospholipase A<sub>1</sub> and B, and mastoparans. Cross-reactivity between the apid and the vespid venoms is limited, but a marked cross-reactivity exists between the different vespid venoms.

The most common areas to be stung are the head, neck, feet, and hands. Stinging is most common during the summer months, and children are often affected. Most patients cannot reliably identify the insect that stung them. Bees and wasps are strongly attracted to dark colors. Therefore eyes, mouth, and nostrils may be selectively targeted. Although stings to the eye are uncommon, when they occur, the cornea is the most common site.

### Physical Examination

**LOCAL.** Both nonallergic and allergic local reactions may occur after a sting. The nonallergic reaction is a non IgE-mediated, direct result of envenomation through mast cell degranulation and histamine release, resulting in the production of a wheal-and-flare response. This response produces erythema, swelling, pain, and itching. These signs and symptoms usually subside in a few hours but may last for several days or exhibit a biphasic reaction where symptoms resolve fully, yet reappear several hours after initial resolution. Localized cutaneous reactions occur in 80% of individuals and are often the sole finding in children following a sting.

Allergic local reactions occur in approximately 17% of people stung by winged Hymenoptera. They consist of erythema and local edema more than 10 cm in diameter; they often persist for 48 to 72 hours, and they may become indurated for a period of up to 5 days. Some patients may experience headache, nausea, or malaise with these reactions.

As mentioned previously, a stinger may sometimes be found at the sting site, which usually indicates a honeybee sting or, in some cases, a yellow jacket sting. Skin and soft-tissue necrosis in the weeks after a Hymenoptera sting have also been reported.

Corneal stings may result in local damage through toxic and immunologic reactions. Stingers retained in the eye may cause corneal edema and ulceration, with striate and toxic keratopathy. Immunologic reactions can result in extensive inflammation and uveitis.

Inflammatory glaucoma may occur as a result of severe uveitis. Severe neuro-ophthalmic complications such as optic neuritis, loss of vision, and cataracts have also been reported.

**SYSTEMIC.** The more common systemic manifestations of an allergic reaction to Hymenoptera stings include urticaria, angioedema, wheezing, shortness of breath, stridor, nausea, vomiting, diarrhea, abdominal pain, malaise, dizziness, and anaphylaxis. Systemic reactions are typically caused by an immunologically induced mast cell or basophil mediator release from an IgE-mediated response. This reaction generally develops within minutes after a sting. Dysphagia, dysarthria, hoarseness, weakness, and confusion also have been described. Effects on the hematologic system include hemolysis with associated hemoglobinuria and hemoglobinemia, thrombocytopenia, and disseminated intravascular coagulation. Respiratory and cardiovascular complications are observed in adults more often than in children. Fatal anaphylaxis is rare, especially in children. However, the sheer number of exposures makes Hymenoptera envenomation the second-leading cause of anaphylactic reactions after penicillin exposure, and it accounts for more deaths in the United States than any other envenomation.

The risk of developing a systemic reaction seems to be increased in the patient with a history of multiple stings or after being stung within a few weeks after a previous sting. The risk is also increased in patients who have a history of anaphylaxis. Their risk of anaphylaxis with subsequent stings is 35% to 60%. The pattern of reaction, however, is difficult to predict. Atopic patients do not seem to be at greater risk of developing systemic complications, but the severity of their symptoms may be greater than in nonatopic individuals. A history of a large local reaction does not reliably predict progression to systemic complications. The risk of subsequent anaphylaxis after a large local reaction is approximately 5% to 10%.

Systemic reactions may also be caused by the direct action of bee venom. In rare cases, serum sickness, vasculitis, encephalopathy, neuritis, and renal disease with or without rhabdomyolysis have been observed. Renal failure or death may occur when 20 to 200 wasp stings or 150 to 1,000 or more honeybee stings have been inflicted. The human 50% lethal dose for honeybee stings has been estimated to be between 500 and 1,200 stings. However, recovery has been reported in children involving incidents of 200 to 1,000 or more honeybee stings. Children are considered to be at high risk because of their failure to perceive the risk, and they are less apt to be able to escape while being stung. The presence of Africanized bees may result in multiple stings resulting in high doses of venom, in turn resulting in hemolysis, thrombocytopenia, rhabdomyolysis (skeletal and myocardial), and acute tubular necrosis. Systemic damage may develop within 24 hours, although delayed onset (2–6 days) has been reported.

### Differential Diagnosis

The differential diagnosis of the local reaction includes other arthropod envenomations, puncture wounds with reactive erythema or cellulitis, or simple cellulitis. The differential diagnosis of systemic reactions includes any

other cause of allergic reaction, reactive airway disease, or infectious processes. Other causes of stridor, wheezing, and allergic reaction should be considered if a sting site cannot be identified.

### Laboratory Studies

No specific laboratory test is useful in the acute management of Hymenoptera stings.

### Management

Insect sting sites should be inspected for the presence of a stinger. Honeybee stingers remain present and will further embed themselves and continue to pump venom after separation from the bee. The venom sac is emptied within 2 minutes of entering the skin; therefore, quick removal of the stinger is imperative. Traditional teaching advocates the removal of the stinger by scraping it with a hard-edged object, such as a credit card, to prevent pressure on the venom sac. Such pressure would theoretically result in an increase in envenomation. However, experimental data show that removal of the stinger with the fingers does not increase envenomation. Rapid removal of the stinger by any means is most effective in minimizing envenomation. Removal of bee stingers that have been embedded for more than 1 minute will not reduce envenomation because most of the venom empties from detached honeybee stingers within 10 to 20 seconds.

Nonallergic local reactions require symptomatic treatment, including cool compresses (ice should not be placed directly on the skin), elevation, and local wound care. No further evaluation is necessary. If local itching is bothersome, then an oral histamine-1 ( $H_1$ ) antagonist such as diphenhydramine may help. Local allergic reactions require care similar to that provided for nonallergic reactions. For very large cutaneous reactions, prednisone (0.5–2 mg/kg/day given in 1–4 doses for 3–5 days) may be useful.

The acute management of a corneal bee sting is aimed at preventing a secondary infection and includes broad-spectrum topical antibiotics, reducing inflammation with topical corticosteroids, treating anterior uveitis, early detection and treatment of inflammatory glaucoma, and providing pain relief. Surgical removal of the embedded stinger is controversial. Pulse corticosteroids may prevent permanent loss of vision.

Mild systemic allergic reactions may be treated with diphenhydramine or another  $H_1$  antihistamine, supportive care, and observation. Epinephrine is the mainstay of therapy for severe systemic allergic reactions, along with  $H_1$  and  $H_2$  antagonists, corticosteroids, and intensive supportive care. A 0.01-mL/kg dose of 1:1,000 aqueous epinephrine solution is injected subcutaneously. The original dose should not exceed 0.3 mL, but it may be repeated in 15 minutes. Susceptible individuals should carry epinephrine self-administered kits when they go outdoors. After a kit is used, medical help should be sought, because the effect of the drug is short lasting. Elevating lower extremities to optimize venous return may be helpful. Severe systemic reactions from direct toxic effects of massive envenomation require intensive supportive care, therapy similar to that for anaphylactic reactions, and careful monitoring for rhabdomyolysis,

thrombocytopenia, cardiac arrhythmias, and renal failure. Dialysis may be required.

Children with systemic reactions who respond completely to therapy in the emergency department should be observed for 6 to 8 hours after the sting because of the possibility of a delayed anaphylactic episode. The mechanism of this delayed complication is not well understood. Children with severe symptoms, including airway, cardiovascular, or pulmonary compromise, or persistent symptoms may benefit from a short course of corticosteroids.

At the time of discharge after a systemic reaction, all patients should be given a prescription for a self-administered epinephrine kit. The patient or caretaker should be instructed in its proper use before discharge from the emergency department. They also should be encouraged to wear a Medic Alert bracelet identifying them as being allergic to insect stings. Patients should be taught how to prevent further stings (see Box 358-1).

The perception that children generally outgrow Hymenoptera sting allergies is not always accurate. Research has found that the long-term risk of a systemic allergic reaction to a sting among patients who do not receive venom immunotherapy is far higher in those with a history of moderate to severe reactions than in those with strictly mild (cutaneous) systemic reactions.

Children who experience extracutaneous systemic reactions should be referred to an allergist for risk analysis and possible venom immunotherapy. Various immunotherapy regimens exist; consequently, susceptible patients may be effectively protected within hours to days, although typical regimens take weeks to months. The immediate access to aqueous epinephrine and a thorough understanding of its administration remain important aspects of care for children undergoing immunotherapy until maintenance doses are reached.

### Fire Ants

#### Characteristics

Approximately 20 species of ants comprise the genus *Solenopsis* (commonly known as fire ants) in the United

#### BOX 358-1 How to Avoid Insect Stings

- Do not disturb nests or hives—have someone else remove them.
- Do not wear perfume, cologne, scented sunscreens, or hairspray when outdoors.
- Use footwear when outside.
- Avoid picnic areas, garbage sites, orchards, fields of clover, and flowerbeds.
- Be extra careful when gardening, and cover the hands and body.
- Avoid trips outdoors if medical help is not readily available or until maintenance immunotherapy is established.
- Do not wear brightly colored clothes or jewelry.
- Install screens on windows and doors to prevent insects from entering the home.

States. Of these, 2 imported species have the most clinical importance: *Solenopsis invicta* and *Solenopsis richteri*. Three common species of native fire ant, *Solenopsis xyloni*, *Solenopsis geminata*, and *Solenopsis aurea*, are less aggressive, have limited geographic range, and have largely been displaced by the imported species.

*S. invicta* is red, 3 mm to 4 mm in length, and native to northern Argentina, Paraguay, and western Brazil. These ants arrived in Mobile, Alabama in the late 1930s and spread aggressively throughout the Southeast from Texas to Virginia, and into California. *S. invicta* is expected to spread north along the West Coast and may reach the Canadian border eventually, displacing native species as it spreads. In infested areas, imported fire ants can make up 90% of the ant population.

*S. richteri* is black, slightly larger than *S. invicta*, and is native to Argentina and Uruguay. *S. richteri*'s importation to southern Alabama preceded *S. invicta* by approximately 20 years, and *S. invicta* has largely displaced *S. richteri*. Currently, *S. richteri* is found only in northeastern Mississippi and northwestern Alabama.

Significant changes in the characteristics of imported fire ants have occurred in the United States. *S. invicta* and *S. richteri* have formed hybrid species with a greater tolerance to cold, which will likely increase their geographic distribution. The spread of fire ants is largely passive, commonly through soil or plant matter.

Imported fire ants are extremely aggressive, which results in a high frequency of envenomation among humans in endemic areas. The literature suggests a 20% to 30% annual attack rate in endemic areas, although rates as high as 58% have been reported. Children are especially vulnerable. The highest sting rate (close to 50%) occurs in persons younger than 20 years. Trespassing into the fire ants' territory or disturbing a nest will incite aggressive, swarming behavior, often resulting in multiple stings. Cases of ants attacking victims indoors are not uncommon. Heavy rains seem to increase this occurrence, although increasingly the ants are noted to nest in human-made structures.

Fire ants bite the skin of their victims with their mandibles, then they arch their bodies to inject venom through a lancet-shaped stinger located at the distal end of their abdomen. If undisturbed, they will continue to sting the victim repeatedly in a circular pattern, using their mandibles as a pivot; venom is injected with each sting.

Fire ant venom differs from bee and wasp venom in that it is mostly composed of alkaloid piperidine hemolytic factors and contains very little protein. However, this protein moiety is responsible for the IgE-mediated allergic reactions sometimes encountered with fire ant stings. Antigenic similarity exists between these proteins and bee and wasp venoms. The alkaloid portion is thought to be responsible for releasing histamine, leading to the common local dermal reactions; it also has some neurotoxic properties.

Fire ant envenomations are becoming an increasingly important public health concern in the United States, resulting in fatalities caused by fire ant-induced anaphylaxis.

### Physical Examination: Signs and Symptoms

**LOCAL.** Stings from imported fire ants often occur on children's ankles and feet in the summer. Stings tend to be multiple and cause immediate local burning and itching. Soon after, the area becomes erythematous and raised. This reaction usually subsides after 30 to 60 minutes. The classic pathognomonic finding of small, sterile pustules (see Figure 358-1) develops between 4 and 24 hours after the sting and is more common with stings of imported fire ants. Pustules may occur in rings or lines consistent with stinging behavior patterns. Pustules usually resolve over 3 to 10 days. Some patients develop a large local reaction similar to that of other Hymenoptera stings. An initial wheal-and-flare reaction evolves into an erythematous, pruritic, warm, indurated area around the sting site. Large local reactions may progress for 48 hours and may not subside for 7 days. The pathophysiologic mechanism of large local reactions is not clear, and they may be confused with cellulitis.

Secondary bacterial infections from excoriation and open erosions are common after fire ant stings. These infections are usually minor and localized. However, sepsis may result from superinfected lesions.

**SYSTEMIC.** Systemic allergic reactions occur in up to 16% of patients treated for fire ant stings, with serious reactions, including anaphylaxis, occurring in up to 2%. Systemic allergic reactions are similar to those associated with other insects and include bronchospasm, angioedema, urticaria, pruritus, laryngeal edema, hypotension, and anaphylaxis. Seizures, mononeuritis, Guillain-Barré syndrome, serum sickness, nephritic syndrome, and worsening of preexisting cardiopulmonary disease have also occurred. The venoms of native and imported fire ants are highly cross-reactive, and phospholipase components of fire ant venom have been shown to be cross-reactive with vespid venom phospholipases. The direct systemic toxic effects of fire ant venom are not well understood. No deaths have been attributed to date to fire ant venom toxicity.

**Figure 358-1** Fire ant stings on adult hand. (From eXtension. Fire ants stings can be serious. Available at: <http://articles.extension.org/pages/69336/fire-ants-stings-can-be-serious#VbaKoPIUJ1A>. Accessed February 9, 2016.)

### Laboratory Studies

The diagnosis of fire ant stings is clinical; no confirmatory laboratory test has been developed.

### Management

Mild local reactions are treated conservatively with cool compresses, oral antihistamines, and wound care. Large local reactions may require oral antihistamines and systemic corticosteroids, and they must be carefully examined to differentiate them from cellulitis. The absence of lymphadenopathy and lymphangitis supports the diagnosis of large localized reaction. Systemic allergic reactions are treated similarly to those from any cause. Epinephrine is the mainstay of therapy, coupled with H<sub>1</sub> antagonists and systemic corticosteroids for symptomatic relief and vigorous supportive care as appropriate. Patients who have experienced severe allergic reactions to stings should be referred to an allergist or immunologist for venom immunotherapy assessment.

### Harvester Ants

Harvester ants (genus *Pogonomyrmex*) belong to the Hymenoptera order, subfamily Myrmicinae, which includes the genus *Solenopsis* (fire ants). More than 20 native species inhabit the United States, but only 3 have been associated with anaphylaxis: *Pogonomyrmex barbatus*, *Pogonomyrmex rugosus*, and *Pogonomyrmex maricopa*. Harvester ants occupy a wide geographic area and are found in the southern and western United States and in Mexico.

Similar to fire ants, harvester ants attach to the skin with their mandibles and envenomate their victim through a sting. Their venom differs from fire ant venom in that it contains a much larger fraction of protein constituents; in this regard, it is more similar to other Hymenoptera venoms.

Unlike imported fire ants, harvester ants do not leave characteristic skin lesions. Their sting resembles that of other insects and may be associated with allergic reactions. Treatment of *Pogonomyrmex* stings is the same as that for other Hymenoptera stings.

## ARACHNIDS

The class Arachnida, which includes spiders, belongs to the phylum Arthropoda. In addition to spiders, other members of Arthropoda include Crustacea (shrimp and crab), Myriapoda (centipedes and millipedes), Chelicerata (a subphylum of Arachnida; spiders and scorpions), and Uniramia (Insecta; bees and flies). Members of Arachnida are distinguished from Insecta by the fact that they have 2 main body regions (cephalothorax and trunk) and Insecta have 3 (head, thorax, and abdomen). Arachnids have 4 pairs of legs to insects' 3, and arachnids are always wingless and lack antennae.

The 2 arachnid orders that will be discussed here are Araneae (spiders) and Scorpionidae (scorpions). Although creatures from both of these orders can inflict envenomations that result in significant morbidity, fatalities are rare. The AAPCC 2013 Annual Report of the NPDS reports no fatalities as a result of spider envenomation. However, poison centers are not consulted for every envenomation, so fatalities

(not reported) from spider envenomation may have occurred.

### Spiders

The order Araneae, which includes all spiders, covers a diverse group numbering 105 families with approximately 40,000 species worldwide. In North America, the spiders most commonly involved in human exposures are *Loxosceles* species (brown recluse spider, also known as the violin spider or fiddleback spider), *Latrodectus* species (black widow spider), and tarantulas. All tarantulas are in the family Theraphosidae. Tarantulas are composed of 13 subfamilies, with multiple genera and species. All spider venom probably evolved for paralyzing prey—insects, other arthropods, or small vertebrates.

Approximately 50 spider species are of medical importance. Most are venomous and can sometimes cause serious injury. The differential diagnosis includes other arthropod bites, skin infections, and injury caused by chemical and physical agents.

Eradicating brown recluse spiders, black widow spiders, and tarantulas is not possible. Most spiders are not aggressive and only bite in self-defense when humans invade their territory or when the spider becomes lost in items such as bedclothes. Tarantulas, which are sometimes kept as pets, pose a risk to the unsuspecting child. Prevention is therefore mostly focused on caution in areas inhabited by spiders. A clean house greatly decreases the risk of spider bite. Refer to the National Pesticide Information Center ([npic.orst.edu/pest/spiders.html](http://npic.orst.edu/pest/spiders.html)) for suggestions on controlling spiders habitating inside and outside the home. Wearing long-sleeved shirts and gloves when outside gardening or wearing long pants tucked into socks when hiking are good preventive measures. While professional extermination may help temporarily, it is not effective for long-term spider control. Insect repellants that contain meta-N, N-diethyltoluamide (DEET) or picaridin may offer some protection.

### *Loxosceles* (Brown Recluse Spider)

**CHARACTERISTICS AND DISTRIBUTION.** In the United States, 11 *Loxosceles* species have been identified. *Loxosceles* are usually found in the Southeast and Southwest United States. Although they have been suspected of traveling in baggage or cargo to other areas, the spider has only rarely been verified outside its normal habitat. In the United States, the brown recluse spider, *Loxosceles reclusa*, is usually responsible for most envenomations. Its natural habitat includes the states of southeastern Nebraska, Kansas, Oklahoma, Texas, Louisiana, Arkansas, Missouri, Kentucky, Tennessee, Mississippi, Alabama, northern Georgia, and southern areas of Ohio, Indiana, Illinois, and Iowa. *Loxosceles* species are not found in Canada. Other *Loxosceles* species include *arizonica*, *deserta*, *devia*, and *rufescens*. Brown recluse envenomations have been shown to exhibit a seasonal correlation, with more bites occurring during the months of April through October. These spiders are hearty and live in dry areas such as woodpiles, rodent burrows, vacant buildings, attics, or closets. They

are reclusive, nocturnal, and nonaggressive unless disturbed. Their web is irregular and common in appearance. Other non *Loxosceles* species spiders that have been reported to cause necrosis ("necrotic arachnidism") include hobo spiders (*Tegenaria agrestis*) from the northwestern United States, yellow sac spiders (cheiracanthium species), and wolf spiders (Lycosidae family) found worldwide.

It should be noted that patients presenting with necrotic arachnidism outside of endemic areas for brown recluse spiders probably were not bitten by a brown recluse spider but were instead bitten by another spider whose venom results in similar clinical manifestations.

The body of the brown recluse spider is oval (10 to 15 mm long, 4 mm wide) and light fawn to dark chocolate in color. The leg span is approximately 25 mm. The eye pattern easily distinguishes them from other spiders. *Loxosceles* differ from other US spiders in that they have 6 eyes arranged in pairs—1 anterior and 2 lateral—instead of 8 eyes. The other often-quoted physical feature, which gives rise to the names *violin spider* or *fiddleback spider*, is a violin-shaped marking on the dorsal side of its cephalothorax, with the violin's neck pointing toward the abdomen. Although this pigmented area is seen on adult spiders, it is not always found on some species in the West and on young spiders.

Bites are usually the result of accidental contact, such as looking through boxes or woodpiles, or contact with linens or clothing in which the spider has become trapped.

#### **PHYSICAL EXAMINATION: SIGNS AND SYMPTOMS.**

**Local.** The bite itself does not cause much discomfort and may go unnoticed. Sometimes a minor stinging or burning sensation may be felt at the site. Erythema, pruritus, pain, and edema typically develop within 2 to 8 hours. These symptoms may be followed in the next 24 to 48 hours by the appearance of a blue-gray halo surrounding the erythematous center. Vesicles or bullae containing serous or hemorrhagic fluid soon follow.

Local ischemia and necrosis result in the formation of a black eschar within 7 to 10 days of the bite. This necrotic area may expand slowly in diameter for weeks, especially in fatty areas that have delicate blood supplies such as the abdomen, buttocks, and thighs. The eschar is shed after 2 to 5 weeks and an ulcer remains that may take weeks to months to heal.

**Systemic.** Systemic manifestations of the bite, called "loxoscelism," are less common than cutaneous manifestations. The most common symptoms are fever, chills, and malaise. Symptoms usually occur within 24 hours of the bite and also may include nausea, vomiting, diarrhea, arthralgia, urticaria or maculopapular rash, hemolytic anemia, disseminated intravascular coagulation, jaundice, renal failure, transverse myelitis, seizures, and shock. Systemic loxoscelism may cause potentially life-threatening complications, especially in children.

**DIFFERENTIAL DIAGNOSIS.** In the absence of a definitive history of spider bites, other diagnostic possibilities must be considered, such as emboli, thrombi, focal vasculitis, envenomation by other insects

or reptiles, fat herniation with infarction, pressure sore, pyoderma gangrenosum, poison oak or ivy, cutaneous manifestation of gonorrhea or herpes simplex, diabetic ulcer, purpura fulminans, erythema nodosum, erythema multiforme, Stevens-Johnson syndrome, or abusive or self-inflicted trauma. Cutaneous anthrax has also been misdiagnosed as *Loxosceles* envenomation.

Other species of spiders have been implicated in the formation of necrotic skin lesions similar to those caused by *Loxosceles*. These are *Argiope* (orb weaver spider), *Chiracanthium* (sac spider), *Lycosa* (wolf spider), *Phidippus* (jumping spider), and *Tegenaria agrestis*. Because other spiders can produce a necrotizing skin lesion, the temptation to diagnose all necrotizing skin lesions as *Loxosceles* bites should be avoided. Positive identification of the spider is important not only for the correct diagnosis, but also to understand better the true clinical course of *Loxosceles* envenomation.

**LABORATORY STUDIES.** No current clinical laboratory study can confirm the presence of arachnid venom-related necrosis. Several research tests, including enzyme-linked immunosorbent assay and passive hemagglutination inhibition test, have been studied, but no such test is in clinical use. Complete blood counts, coagulation profiles, electrolytes, and renal function should be monitored in systemic illness.

**MANAGEMENT.** Management is controversial because the unpredictable natural course of the wounds makes prospective trials difficult. Serial observations, cleansing, cool compresses, splinting of the affected extremity, and tetanus prophylaxis are commonly suggested measures. Symptomatic relief with antipruritics and analgesics may be useful in some cases. Patients with exclusively local findings likely do not need hospital admission. Patients (especially children) with systemic symptoms should be admitted and monitored for signs of hemolysis.

Different therapies have been proposed, including systemic corticosteroids, antibiotics, antihistamines, colchicine, dapsone, electric shock, hyperbaric oxygen, metronidazole, and surgical excision and skin graft. None of these therapies is of proven efficacy for *Loxosceles* envenomation. Although the most suitable therapy in children is unclear, general agreement exists on delaying any surgical repair of skin defects until the necrotic demarcation is discrete and no further spread occurs. This period is approximately 8 weeks.

#### ***Latrodectus (Black Widow Spider)***

**CHARACTERISTICS.** Although both male and female black widow spiders have venom, only the female spider has fangs powerful enough to bite through skin and envenomate humans. Black widow spiders are among the largest spiders in the world, with a leg span of 40 mm and a body of 1.5 cm. The mature female spider is black, with a red or orange hourglass-shaped marking on the ventral surface. The immature female spider may be red, brown, or cream in color, and the hourglass marking may be cream colored or even incomplete.

The web, usually built close to the ground in dimly lit, moist areas, is distinguishable by its irregular pattern. It may be found in barns, outhouses, lumber

piles, and sheds where insects are plentiful. Bites are usually a result of the spider being disturbed and acting in self-defense.

While black widow spider envenomation remains a significant health problem in the US, there are no cases of death resulting from envenomation by the widow species in the US.

**DISTRIBUTION.** *Latrodectus* spiders are found in both temperate and tropical climates throughout the world. There are 5 species found in the United States; Alaska is the only state that does not have this genus. The most common spiders implicated in bites are *Latrodectus mactans*, *Latrodectus variolus*, and *Latrodectus hesperus*. Envenomations by any of these species result in the same clinical syndrome.

**PHYSICAL EXAMINATION: SIGNS AND SYMPTOMS.**

**Local.** A bite may go unnoticed or may be experienced as a pinprick or burning sensation. Two small puncture lesions may be visible. Within 30 minutes, pain develops at the site and in the regional lymph nodes. Central pallor at the bite site with surrounding erythema has been described. Unlike the bite of *Loxosceles*, the black widow bite does not usually induce an impressive inflammatory response. An unusual reaction may include compartment syndrome, which may improve after antivenin administration.

**Systemic.** The onset of systemic symptoms, known as “latrodectism,” is often sudden, with crampy, skeletal muscle pains in the legs, abdomen, back, and chest and associated autonomic dysfunction. The most common systemic signs and symptoms are generalized abdominal pain or back pain, local or extremity pain, hypertension, both systemic and local diaphoresis, and isolated abdominal or chest pains. Nausea and vomiting and tachycardia may also be present. Restlessness, salivation, bronchorrhea, priapism, urinary retention, periorbital edema, tremor, and convulsions may also be seen. Abdominal rigidity may mimic peritoneal irritation. Respiratory paralysis, heart failure, and myocarditis have been reported. In children, symptoms include abdominal pain, hypertension, muscle complaints, target-shaped skin lesions, and irritability or agitation. Treatment may alleviate symptoms.

Patients who do not receive antivenin may experience protracted symptoms lasting for several days to a week. Symptoms can include fatigue, weakness, paresthesias, generalized aches, diaphoresis, headache, sleeplessness, excessive sweating, impotence, mental status changes, and transient hemiparesis.

The primary protein component of *Latrodectus* venom is  $\alpha$ -latrotoxin. This protein binds to motor end plate receptors, causing increased synaptic concentration of catecholamines. This excess catecholamine results in characteristic muscle cramps, hypertension, nausea, vomiting, weakness, tremors, and malaise.

Historically, it was posited that black widow spider venom could cause spontaneous abortion or preterm labor in a pregnant patient. This belief has not been documented in modern times. Black widow envenomation in pregnant women is a rare occurrence, and short-term outcomes seem favorable.

**LABORATORY STUDIES.** No specific laboratory test helps establish a diagnosis. Leukocytosis and

hyperglycemia are common. Creatine phosphokinase may be increased as a result of increased muscle activity. Serum calcium levels are normal.

**DIFFERENTIAL DIAGNOSIS.** The causes of acute abdominal pain should be part of the differential diagnosis. Of interest is the close resemblance of the autonomic hyperactivity seen after black widow spider bites and those seen in organophosphate poisoning. The pain can also mimic myocardial infarction.

**MANAGEMENT.** While latrodectism can be severe, in the United States, most symptomatic black widow envenomations reported to the NPDS have minor sequelae, and most symptoms resolve after proper analgesia. Most black widow spider bites require only cool compresses, elevation of the affected extremity, tetanus update (if needed), and analgesics. In more severe cases, the administration of oxygen, cardiac monitoring, and intravenous access are suggested.

Muscle cramps may be relieved with opioids and muscle relaxants. Diazepam, methocarbamol, and calcium gluconate have been used with varying results. The efficacy of 10% calcium gluconate has been questioned. Retrospective analyses of the literature failed to find any significant relief in pain following administration of calcium gluconate, and for this reason calcium is not recommended. Patients who do not receive antivenin gradually improve over the next 12 to 48 hours, and some patients may experience protracted symptoms.

*Latrodectus* antivenin of equine origin is available and neutralizes venom from all related species. Because of the concern for fatal anaphylaxis, patients should be tested for horse serum hypersensitivity before it is administered. It should be considered in cases of severe envenomation when the patient shows evidence of respiratory distress, marked hypertension, and cardiovascular compromise. *Latrodectus* antivenin should also be considered in pregnant women and for protracted symptoms that do not respond to analgesics and muscle relaxants. The response is usually dramatic after antivenin infusion. The administration of antivenin may decrease the length of the hospital stay and prevent lingering neurologic complications.

Unfortunately, there is limited inventory of this antivenin and there are limitations on distribution. For safety and supply issues, alternative antivenin pursuits have led to the creation of highly purified equine F(ab')<sub>2</sub> antibody preparation (Analatro), commercially available in Mexico and being studied in trials in the United States. A randomized, placebo-controlled, double-blind, clinical trial was conducted in 12 academic emergency departments in patients older than 10 years who experienced moderate to severe pain following a suspected black widow spider envenomation. Although the overall reduction in pain was similar for antivenin- and placebo-treated subjects, antivenom reduced pain more rapidly than placebo. No significant adverse events occurred in either group. At the time of press, Analatro is not yet approved for general distribution and use.

**Tarantulas (Mygalomorphs)**

**CHARACTERISTICS.** Tarantulas, more appropriately called *mygalomorphs*, are considered primitive forms

of true spiders. In the United States, the species spends most of the daytime hours in burrows, emerging to hunt at night. They are docile, and bites are unusual. Body size varies; they can reach up to 10 cm in diameter. These spiders possess large fangs that point straight down and require them to lean back on their hind legs to bite—a characteristic defensive posture. More than 30 species of tarantulas are found in the tropical and subtropical desert areas of the southwestern United States. Some North American and foreign species are kept as pets. Children who keep tarantulas as pets should be instructed on identifying defensive behavior.

**PHYSICAL EXAMINATION: SIGNS AND SYMPTOMS.**

Most bites are no more severe than a bee sting and occasionally result in local erythema, swelling, and pain. Nausea and vomiting may occur from the bite. Some genera (*Lasiadora*, *Grammostola*, *Acanthoscurria*, and *Brachypelma*) are capable of releasing urticaria-producing hairs from their abdomen by rubbing their hind legs on the area. This event can result in local histamine release with mild pruritus. However, the itching can last for weeks. The hairs may cause itching in eyes or airways and cause considerable discomfort. Hairs embedded within the cornea may cause chronic keratitis and retinitis.

**MANAGEMENT.** Local wound care and a tetanus update are all that is needed in most cases; antihistamines and oral analgesics may be helpful. Adhesive tape or irrigation with saline solution may be used to remove the urticaria-producing hairs from the skin. Steroids may be indicated for significant ophthalmological complications from the hairs of a tarantula.

## Scorpions

### Characteristics

*Centruroides exilicauda*, formerly *Centruroides sculpturatus*, or the bark scorpion, is the only medically relevant species of scorpion in the United States. Envenomation may be life threatening, especially in infants and children. The bark scorpion's habitat is Arizona and adjacent states in the southwestern United States. Scorpions are found in Arizona and parts of southern California, Nevada, New Mexico, and Texas. *C. exilicauda*, which is considered a climbing scorpion, can be sighted on trees, fence posts, and rocks and in cracks and trash piles. It measures 1.3 to 7.5 cm in length and envenomates its victim with a stinger located at the tip of its tail. The venom is a potent neurotoxin that activates neuronal sodium channels and results in excessive firing of the affected neurons, including both adrenergic and parasympathetic systems. Patients may exhibit both adrenergic and cholinergic symptoms.

Stings usually result from accidental contact with a scorpion trapped in linen or clothing or during outdoor play. Not all stings result in clinical evidence of envenomation. Although most stings take place in scorpion-endemic areas, scorpions can be accidentally transported to other areas by travelers.

### Physical Examination: Signs and Symptoms

**LOCAL.** Pain always occurs at the sting site with or without paresthesias, especially with species other

than *Centruroides*. In mild envenomations, pain may be the only symptom. Infants may exhibit this symptom as unexplained or prolonged crying. Local erythema and swelling may surround a small puncture wound, but the sting site is often unidentifiable. Paresthesias and pruritus are also frequent.

**SYSTEMIC.** Systemic manifestations of *Centruroides* scorpion envenomation can be dramatic, usually develop within 60 minutes of the sting, and persist for days. They tend to be more common in children younger than 10 years. Cardiovascular findings include tachycardia or bradycardia. Children may experience central nervous system dysfunction, a finding that is rare in adults. Severe hypertension may be present in one-third to two-thirds of the victims. Hypertension is sometimes associated with acute hypertensive encephalopathy. Heart failure and acute lung injury may also be seen. An ischemic electrocardiographic pattern may be present. Hypertension may not respond to medical management.

Echocardiographic, scintigraphic, and hemodynamic evaluations reveal hypodynamic ventricular motion with decreased systolic performance. Pulmonary edema is a common feature and is likely because of decreased ventricular performance in the setting of increased venous return, arterial hypertension, kinin-induced increased permeability of the pulmonary vasculature, and impaired left-ventricular filling caused by tachycardia. Electrocardiographic changes are common and include nonspecific ST-T changes or ST elevation or depression consistent with myocardial infarction.

Pathologic cardiac specimens show evidence of ischemia and direct toxicity. The primary mechanism of cardiovascular toxicity is thought to be the result of excessive stimulation of the autonomic nervous system, with the sympathetic influence generally being greater than the parasympathetic. Cardiac effects may also be mediated by electrolyte changes, in particular a relative hyperkalemia.

Neurologic toxicity in the form of cranial nerve abnormalities includes blurred vision, tongue fasciculations, nystagmus, and characteristic opsoclonus-like roving eye movements. Bulbar muscle dysfunction including dysarthria, stridor, pharyngeal spasm, and dysphagia may also be present.

Excessive cholinergic stimulation results in sweating and vomiting. Profound sialorrhea may be evident because of increased cholinergic transmission and difficulty swallowing secretions.

Skeletal muscle findings include twitching or jerking of the extremities, which in some cases may be severe enough to be mistaken for seizure activity. Rhabdomyolysis may result from this event. Nystagmus may be present. Seizures and agitation may also occur.

In pregnant patients following scorpion envenomation, the limited available literature suggests that adverse outcomes are largely related to venom effects to the mother rather than to the fetus in utero.

### Differential Diagnosis

Two factors make establishing the correct diagnosis difficult. The first is that the sting site may not be

identifiable; the second is that the child may not be able to communicate the history of a sting clearly. Seizure disorders, latrotoxicity, intra-abdominal catastrophes, phenothiazine or cholinergic (organophosphate) poisoning, and allergic reactions are some of the differential diagnostic possibilities. Some children have been misdiagnosed as having asthma in the presence of wheezing and respiratory distress. In infants presenting with unexplained crying and restlessness, the differential is further broadened and well discussed elsewhere in the pediatric literature. The characteristic eye movements (if present) in high-grade scorpion envenomation can distinguish this diagnosis from others.

On rare occasion, in *C sculpturatus*-endemic areas, envenomation should be included in the differential when methamphetamine intoxication is being considered.

The progression of symptoms is not predictable; the progression to serious symptoms usually occurs in less than 5 hours, if at all. Numbness, tingling, and pain may persist for 2 weeks. The duration of symptoms has been found to be inversely related to the age of the patient.

Laboratory Studies

Scorpion envenomation is a clinical determination. No confirmatory laboratory test exists. Leukocytosis, cerebrospinal fluid pleocytosis, and increased creatine phosphokinase have been reported.

Management

The treatment of scorpion envenomation is primarily supportive, with the use of cold compresses, tetanus prophylaxis, and analgesics for mild to moderate envenomation. Severe cases require aggressive supportive therapy, which may include endotracheal intubation for airway protection or hyperthermia, benzodiazepines for the treatment of seizures or agitation, and narcotic analgesics for pain control. Although various adjunctive therapies have been tried, no clear standard therapy has been developed. Antihypertensives, including calcium-channel blockers, hydralazine, prazosin, and captopril, have all been used. At present, afterload reducers such as angiotensin-converting enzyme inhibitors, calcium-channel blockers, or prazosin are front-line therapeutic agents for hypertension. Concern about reflex tachycardia has led some physicians to favor prazosin and captopril. The use of diuretics for pulmonary edema is controversial. Atropine

may be used with caution if cholinergic symptoms become severe. Atropine may improve hypersecretion, obviating more aggressive therapy. Treatment should be guided by thorough hemodynamic monitoring. Neither corticosteroid therapy nor systemic antibiotics are routinely recommended.

Before 2011, scorpion antivenin was not widely available. A horse serum-derived whole immunoglobulin preparation used to be available in Arizona in limited supply; however, manufacture of this product ceased. Because of its minimally refined nature and high protein dose, there was a high rate of hypersensitivity and serum sickness. In 2011, Anascorp, *Centruroides* (Scorpion) Immune F(ab')<sub>2</sub> (Equine) Injection was approved after priority review as an orphan drug in the United States by the US Food and Drug Administration (FDA) (see 3-vial dosing guidelines in Table 358-2). The effectiveness of Anascorp was based on results from a randomized, double-blind, placebo-controlled trial of 15 children with neurologic findings consistent with scorpion envenomation. These signs resolved within 4 hours of treatment in the 8 subjects who received Anascorp, but in only 1 of the 7 subjects who received the placebo. Anascorp also reduced the need for concomitant sedation with midazolam and reduced the levels of circulating unbound venom. The safety of equine F(ab')<sub>2</sub> antivenin was evaluated prospectively during development of the product for a biological license application through the US FDA, in 1,534 patients aged 0.1 to 90.5 years who received antivenin. The antivenin was well tolerated. Only 3 patients had acute reactions to antivenin infusion, and 8 had rashes suggestive of Type 3 immune reactions. No patient developed the full syndrome of serum sickness. Two women were treated for envenomation during their first trimester of pregnancy; one of these women suffered spontaneous abortion.

Routine use of the new antivenin is not indicated for every scorpion-envenomated patient because of the risk of reactions and high cost considerations. Prompt supportive care is the mainstay of therapy. After implementing symptomatic and supportive care, patients who have persistent signs of severe envenomation or neurotoxicity should be strongly considered for antivenin therapy.

SNAKES

There are over 2,500 species of venomous snakes in the world; approximately 30 species are known to

exist in North America. In 2013, the AAPCC NPDS recorded more than 6,000 total snake envenomations (339 in children younger than 5 years), with more than half belonging to the Crotalinae family. All 3 of the deaths reported from snake envenomations were caused by Crotalid bites. The venomous snakes of North America can be divided into 2 families: Viperidae (subfamily Crotalinae) and Elapidae. The Crotalinae includes genera *Crotalus* (rattlesnakes), *Agkistrodon* (water moccasins or cottonmouths and copperheads), and *Sistrurus* (pygmy rattlesnakes and Massasauga rattlesnakes). As a group, these snakes are known as *pit vipers* because of a heat-sensitive pit found behind and below their nostrils. Snakes use this organ to locate the victim of a strike. The Elapidae family includes coral snakes and the nonindigenous cobras and mambas.

### Epidemiologic Features

#### Type of Snake

Envenomations by snakes in North America are overwhelmingly caused by indigenous Crotalinae; Elapidae constitute less than 2% of envenomations. Nonindigenous snakes in North American zoos or kept as exotic house pets are responsible for only a small percentage of envenomations. All sea snakes are venomous, but fortunately, none inhabit the coastal waters of North America.

#### Host Factors

The typical snakebite victim is a young adult white male between 17 and 27 years of age who is bitten while handling or playing with a snake. Many of those bitten have a blood alcohol level of more than 0.1%. Fewer than one-half of rattlesnake bites occur before an encounter with a snake was recognized or while the person was attempting to move away from the snake. Most bites in the United States occur in the southwestern states.

#### Body Area

Most bites are inflicted on the upper extremity, including fingers, hand, and arm. Other, less commonly affected sites are leg or foot and torso. Given the high percentage of bites experienced while the snake was intentionally being handled, these sites are less surprising than reports of snakebites to the tongue and the glans penis.

#### Mortality

The number of deaths from snakebite in the United States ranges from 0 to 14 per year. Most snakebite deaths are associated with the absence of medical care, bites to the face or throat, errors in medical management, or the presence of an underlying medical condition. Children are at increased risk for serious sequelae because of their lower body mass and the relatively high venom dose per kilogram of body weight compared with adults.

#### Prevention

Historically, Native Americans used numerous plants, animal tissues, oils, and excrement to prevent snakebites. Box 358-2 provides current practical suggestions for preventing snakebites that are based on the epidemiologic

### BOX 358-2 Snakebite Prevention

1. Differentiating poisonous from nonpoisonous snakes is impossible without years of experience. Therefore, children should not approach, disturb, play with, capture, or kill any snake. These practices are dangerous for both the human and the snake.
2. Children should not put their hands or feet in places they cannot see. Children should not put their hands or feet anywhere without first looking.
3. Snakes often can be found under rocks, boulders, fallen trees, fences, rubbish piles, and boats that have been left on shore for several hours; in tall grass and heavy underbrush; or sunning themselves on logs, boulders, trees, walls, or cliffs. Extra caution should be used in these areas.
4. The striking distance of a snake is roughly half its length. Children should be taught to keep a safe distance from snakes.
5. The striking reflex remains intact for up to an hour after the snake has died. Dead snakes or snake parts should not be handled directly for this reason.
6. Rattlesnakes are nocturnal feeders and therefore are active after dark. Never gather firewood after dark. Campsites should be set up on open ground, never near wood, rubbish piles, swampy areas, or the entrance of a cave.
7. Children should wear boots when walking in areas endemic for snakes.
8. Children should not be allowed to walk alone in an area endemic for snakes.
9. Children should not be allowed to swim in waters known to be infested with snakes.
10. Once bitten, everyone present should get away from the snake as quickly as possible. The benefit of identifying the snake is small in comparison to the risk of additional bites.

mechanism of these injuries and the medical community's understanding of snake behavior.

### Characteristics

Some key characteristics can help distinguish between venomous and nonvenomous snakes; however, overlap and exceptions create difficulty in distinguishing the difference (see Table 358-3). Crotalinae are characterized by a heat-sensing pit on either side of the head between the eye and the nostril. This apparatus is used to locate and estimate the size of prey and predators. The snake can estimate a venom dose in accordance with the size of the prey that is to be immobilized, killed, and digested.

Crotaline snakes have highly mobile, retractable, hollow fangs that function similarly to a hypodermic needle. They usually penetrate to subcutaneous tissue, but large snakes can reach a depth of 8 to 19 mm. The speed of a pit viper's strike has been clocked at 8 feet per second, and the animal can reach distances of approximately one-half of its body length. Consequently, larger snakes may penetrate dermal or subcutaneous structures and deposit venom into the muscle. Venom

**Table 358-3** Characteristics of Venomous Versus Nonvenomous Snakes<sup>a</sup>

CHARACTERISTIC	VENOMOUS SNAKE	NONVENOMOUS SNAKE

is generally absorbed through the lymphatic system, although rare cases of intra-arterial and intravenous deposition of venom have been reported. For an envenomation to take place, the pit viper must be venomous at the time of the strike, penetrate the skin, and inject venom during penetration. Approximately 20% to 25% of pit viper bites are *dry*, meaning they do not result in envenomation.

Crotaline venom is a complex mixture of biologically active proteins and peptides capable of damaging vascular endothelial cells, leading to increased permeability to plasma and erythrocytes into the extravascular space, which can ultimately result in hypotension and shock. This process may also occur in the lungs, myocardium, kidneys, peritoneum, and central nervous system. Other enzymes specific to pit viper venom include proteolytic enzymes, hyaluronidase, thrombin-like enzymes, phospholipase-A<sub>2</sub>, L-amino acid oxidase, collagenase, RNase, DNase, and arginine ester hydrolase. Venom is spread throughout the body as a result of the action of hyaluronidase and its integrity-reducing effect on connective tissue.

Pit viper venoms, which are derived from the salivary glands, are designed to immobilize and digest prey. Prominent effects include direct tissue injury resulting from enzymatic degradation. Local inflammatory responses are exaggerated by metalloproteinases, which cleave pro-tumor necrosis factor alpha (TNF-α), releasing activated TNF-α. Myotoxin-α acts to increase intracellular calcium in skeletal muscle, resulting in prolonged contraction and necrosis. The presence of systemic myotoxin-α and phospholipase-A<sub>2</sub> is thought to be the cause of myonecrosis and rhabdomyolysis. Phospholipids A<sub>2</sub> also increase permeability of red blood cell membranes, changing their morphology and potentially causing hemolysis. One of the byproducts of the enzymatic action of phospholipase-A<sub>2</sub> is lysolecithin, which can damage mast cell membranes and cause histamine release.

A coagulopathy caused by fibrinolysis and thrombin-like peptide actions may result in isolated defibrination. Thrombocytopenia occurs as a result of platelet aggregation at sites of tissue injury and from a direct effect of venom on individual platelets, particularly rattlesnake venom. Given that thrombocytopenia and defibrination both occur independently, the physician must distinguish between these processes occurring

### BOX 358-3 Indigenous Locations for North American Pit Vipers

#### SOUTHEAST

- Cottonmouths and copperheads<sup>a</sup>
- Eastern diamondback (*Crotalus adamanteus*)
- Timber (*Crotalus horridus*)
- Southeastern pygmy rattlesnakes (*Sistrurus miliarius barbouri*)

#### MIDWEST

- Cottonmouths and copperheads<sup>a</sup>
- Eastern diamondback (*Crotalus adamanteus*)
- Timber (*Crotalus horridus*)
- Prairie (*Crotalus viridis*)

#### NORTHEAST

- Cottonmouths and copperheads<sup>a</sup>
- Eastern diamondback (*Crotalus adamanteus*)
- Timber (*Crotalus horridus*)
- Eastern Massasauga rattlesnakes (*Sistrurus catenatus*)

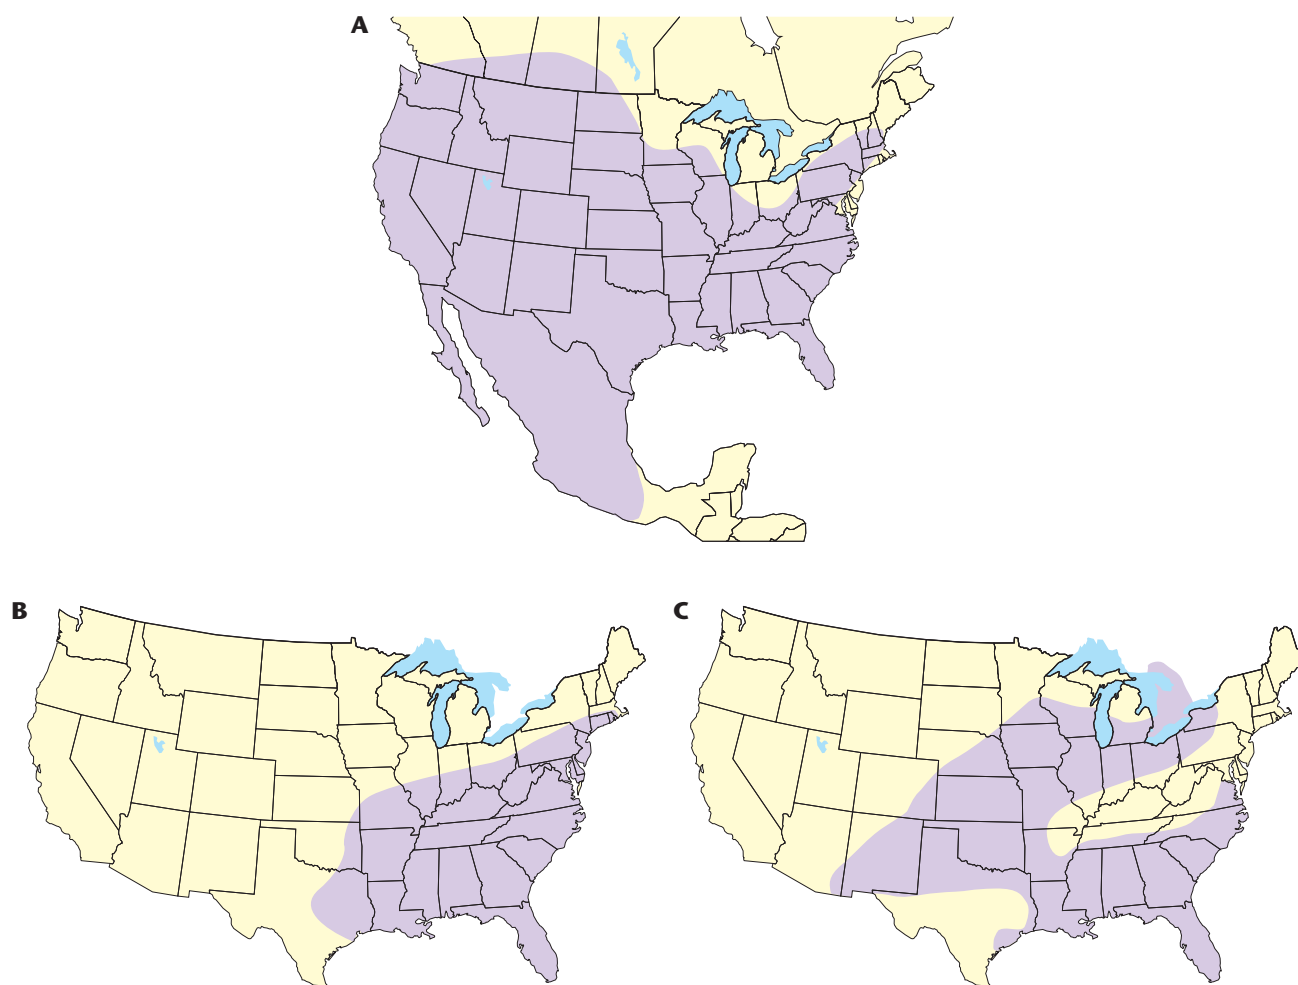

#### NORTHWEST

- Great Basin (*Crotalus viridis lutosus*)
- Northern Pacific (*Crotalus viridis oregonus*)

#### SOUTHWEST

- Western diamondback (*Crotalus atrox*)
- Sidewinder (*Crotalus cerastes*)
- Rock (*Crotalus lepidus*)
- Speckled (*Crotalus mitchellii*)
- Black-tailed (*Crotalus molossus*)
- Twin-spotted (*Crotalus pricei*)
- Red diamond (*Crotalus ruber*)
- Mojave (*Crotalus scutulatus*)
- Tiger (*Crotalus tigris*)
- Prairie (*Crotalus viridis*)
- Grand Canyon (*Crotalus viridis abyssus*)
- Southern Pacific (*Crotalus viridis helleri*)
- Great Basin (*Crotalus viridis lutosus*)
- Ridge-nosed (*Crotalus willardi*)

<sup>a</sup>Agkistrodon speciesDerived from Russell FE. *Snake Venom Poisoning*. Great Neck, NY: Scholium International, Inc; 1983.

simultaneously and true disseminated intravascular coagulation, which may also occur. Neurotoxins are also present in varying degrees, notably in the Mojave and timber rattlesnakes, and can produce weakness and paralysis, as well as myokymia, which appears as involuntary wormlike muscle movements under the skin. The cause of crotaline-induced neurotoxicity remains under study.

The notion that juvenile rattlesnakes are more dangerous than adult snakes is a misconception. The venom of some juvenile rattlesnakes may be slightly more toxic, but larger rattlesnakes are capable of delivering more venom in a single bite. Additionally, venom composition seems to change as the rattlesnake matures. Specifically, phospholipase- $A_2$  activity decreases with the snake's age, but proteolytic activity increases. The clinical relevance of these differences is uncertain.

### Distribution

Native venomous snakes have been identified in all states except Alaska, Hawaii, and Maine.

Box 358-3 lists the indigenous locations for North American pit vipers. See also Figure 358-2.

### First Aid

Commonly accepted guidelines for snakebite first aid are summarized in Box 358-4. Other forms of first aid are controversial (see treatments in number 7 in the table) and are discussed here because the physician may see patients who are less damaged by the snake than by the field treatment of well-meaning but untrained (and possibly inebriated) attendants.

### Identification

The helpfulness of identifying the type of snake is controversial. Snake parts should never be handled directly because the bite reflex in recently killed or decapitated snakes can remain intact, rendering them capable of biting even when they are dead. Snakebite victims should be rushed to medical attention, and the rescue party should not expose themselves to risk while trying to find and identify the snake. If medically necessary, a herpetologist from a zoo or aquarium may be able to help with positive identification.

### Cryotherapy

Cryotherapy is a form of snakebite treatment that is theorized to constrict blood flow, thus diminishing

### BOX 358-4 First Aid for Snakebites (Pre-Hospital care)

1. Don't waste significant time trying to identify the snake. If possible and you are able to keep yourself and others safe and out of the snake's striking range, take a photo of the snake to capture approximate size and characteristics.
2. Move the patient as little as possible.
3. Mark the victim's skin with an indelible pen to indicate the area of swelling and the time. Repeat this every 15 minutes.
4. Remove rings, watches, and constrictive clothing.
5. Immobilize the affected limb by splinting as if for a fracture, and keep the limb below the level of the heart if possible.
6. Regardless of early symptoms, transport the victim to the nearest medical facility at a safe speed.
7. Avoid the use of ice (tissue damage), tourniquet/pressure bandages, aspirin (anticoagulation), alcohol or sedative drugs (vasodilation), or stimulants such as caffeine (acceleration of venom absorption).
8. Do not use any extraction devices or have anyone attempt to suck out the venom. This will prevent further damage to tissue as well as preventing a second exposure (caregiver) to the venom.
9. As soon as possible, start basic life support, including volume expansion and Trendelenburg position for patients with hypotension.

systemic venom absorption and inactivating the venom enzymes and proteins. Freezing does not inactivate snake venom. Cases of limb ischemia have been reported from cryotherapy. Cryotherapy should not be used to treat snake envenomation.

#### Incision and Suction

Incision at the bite site and suction has shown mixed results in clinical and laboratory trials. Complications of incision and suction include damage to underlying neurovascular structures, increased rate of wound infection, and further tissue damage. Given that no clear benefit has been demonstrated, incision and suction should not be performed.

#### Constricting Bands

Constricting bands that impede blood flow should not be used. Only loose-fitting bands placed in an effort to reduce lymphatic flow have been advocated, but these have not been shown to be of clear benefit. Thus, constricting bands of either type should not be used. Although the routine use of an extractor device for care in the field is not advocated, patients who have an extractor or suction device in place should not remove it until they arrive at a health care facility.

#### Immobilization

Splinting of the affected extremity and placing it in a position below the level of the heart should be performed without delaying transport to a medical

facility. Patients should be kept as calm as possible during transport because agitation hastens venom distribution.

#### In-Hospital Care

Information elicited in the medical history of known envenomations includes the size and species of the snake, the circumstances of the bite (eg, through clothing, alcohol related), the number of bites and body area affected, first-aid methods used, time of bite and transport time, previous snakebite history, allergy to horse- or sheep-derived products (eg, drugs, food, animal products), and tetanus immunization status. The patient's coexisting medical conditions, with special attention paid to the cardiovascular, pulmonary, and neurologic systems, should be factored into the clinical management of the exposure. Snakebites from exotic (nonindigenous) species, which usually occur in zoo employees or in those illegally keeping the snake as a house pet, also occur, and physicians must address this issue as part of the history-gathering process. The clinical presentation and medical management of an exotic bite may differ from bites of North American poisonous snakes.

#### Physical Examination: Signs and Symptoms

##### Local

Local signs and symptoms usually include the presence of 1 or more fang marks, pain, edema, ecchymosis, and erythema from 15 minutes to 4 hours after the bite. The notion that copperhead envenomations are generally benign as compared with other pit viper envenomations is not true. Although ecchymosis and swelling are considered to be less common after copperhead bites, significant local injury after copperhead envenomation has been reported. Pain is present in more than 90% of envenomations, although an exception is the Mojave rattlesnake, the bites of which inflict little or no pain. Fang marks typically have ragged edges, but these edges may be obscured as a result of trauma experienced during the flight from the snake or trauma resulting from first-aid attempts. Because of the presence of hemorrhagic toxins in pit viper venom, blood may ooze from the puncture sites, and hemorrhagic bullae may develop. Muscle necrosis also may become apparent. Lymphangitis and lymphadenopathy with tender regional lymph nodes and warmth in the injured body part may occur as a result of the lymphatic spread of venom components.

##### Systemic

Typical systemic findings may include malaise, weakness, lightheadedness, diaphoresis, visual disturbances, nausea, vomiting, syncope, myokymia, perioral paresthesias, and a metallic or minty taste. More severe systemic effects include altered sensorium, acute respiratory distress syndrome, respiratory depression, hemodynamic instability leading to circulatory collapse, and renal failure. A consumptive coagulopathy is often present in serious envenomations characterized by hemolysis, an unmeasurable international normalized ratio (INR) and activated partial thromboplastin time, hypofibrinogenemia, the presence of fibrin degradation products, thrombocytopenia, and generalized

hemorrhage. When combined with defibrination, venom-induced thrombocytopenia may appear as, or be a contributing factor to, disseminated intravascular coagulation. The Mojave rattlesnake may cause more neurotoxicity, specifically myokymia, than other rattlesnakes.

### Laboratory Studies

Laboratory studies have been found to be of only minor assistance when the severity of rattlesnake envenomation is being assessed. Laboratory studies may be useful early in the course of treatment, however, in determining whether an envenomation has actually occurred. Studies should include a metabolic panel, creatinine kinase, a complete blood count with differential, red blood cell morphology (to assess for spherocytosis), INR and prothrombin time, plasma thromboplastin time, fibrinogen levels, fibrin-split products, and platelet count. If these studies reveal any abnormalities, or if the patient has clinical symptoms, then envenomation must be assumed, and an analysis of electrolytes, urinalysis, blood urea nitrogen, and a blood type and cross-match should be performed. Patients may require further testing as the clinical situation dictates.

### Disposition

After a pit viper envenomation, a patient should be observed in the emergency department for a minimum of 8 hours. The absence of symptoms, systemic findings, or laboratory abnormalities after 8 to 12 hours of observation suggests a “dry bite” in which no venom was released following envenomation. Patients who remain asymptomatic and whose coagulation study results are normal may then be discharged with instructions to return if symptoms develop. Not all patients require treatment with antivenin; many envenomations resolve completely with adequate symptomatic and supportive care. Symptomatic patients and all patients treated with antivenin should be admitted, preferably to an intensive care unit.

### Local Therapy

Local wound care includes gentle irrigation, nonconstrictive immobilization, elevation of the bitten extremity, and close observation for a minimum of 8 to 12 hours to evaluate for the onset or progression of symptoms and thus determine whether antivenin is indicated. Circumferential measurements at several points along the affected limb should be performed at baseline and regularly repeated to monitor the progression of swelling. Intercompartmental pressures should only be measured in cases when the patient's symptoms are consistent with compartment syndrome. The snakebite extremity may seem nearly identical to an extremity with a compartment syndrome. In cases of suspected compartment syndrome, the clinical diagnosis requires objective evidence of increases in compartment pressure to more than 30 mm Hg. Fasciotomy has not been shown to be of benefit, may lengthen the hospitalization, and cause significant long-term morbidity. No evidence exists for the use of excisional therapy, and its use is discouraged. Digital dermatomy may be indicated on clinical grounds.

### Shock

Patients may have a marked decrease in intravascular volume as a result of hemorrhage, third-space fluid loss, vomiting, and diaphoresis. Crystalloid replacement should begin immediately in envenomated patients. In the case of hypotension caused by extravascular fluid shifts or hemorrhage, antivenin therapy should be considered.

### Fluid and Electrolyte Abnormalities

Extensive third-space fluid loss may cause fluid and electrolyte imbalances. Electrolyte and urine output monitoring with fluid and electrolyte replacement with crystalloid is essential.

### Hematologic Complications

The treatment of thrombocytopenia and anemia (caused by hemolysis) may require multiple transfusions. Transfusions of fresh-frozen plasma and cryoprecipitate may be required in severely envenomated patients. Therapy with blood products is rarely effective, however, in the absence of antivenin therapy. Treatment with coagulation factors may actually worsen the coagulopathy by adding more substrate for unneutralized venom, thus increasing the levels of degradation products, which are also anticoagulants. Thrombocytopenia often corrects with antivenin therapy alone, and clotting factor levels rarely improve when blood products are provided without antivenin. Disseminated intravascular coagulopathy caused by snakebite does not respond to heparin; antivenin is the treatment of choice.

### Use of Antivenin

The sole antivenin used from 1954 to 2000 in the United States to treat pit viper envenomations was antivenin (*Crotalidae*) polyvalent (ACP). It was produced by injecting horses with venom from *Crotalus adamanteus*, *Crotalus atrox*, *Crotalus durissus terrificus*, and *Bothrops atrox*. A high incidence of serum sickness and serious allergic reaction was associated with its use. Skin testing was necessary before administration of antivenin. After December 2000, crotaline polyvalent immune Fab (ovine) antivenin (CroFab, BTG International Inc, West Conshohocken, PA) was released. CroFab has replaced the horse serum-based antivenin ACP as the drug of choice for crotaline envenomations, and ACP is no longer manufactured. CroFab is a purified ovine polyvalent Fab immunoglobulin fragment product produced by immunizing sheep with venoms of 4 crotaline snakes: *C. adamanteus* (eastern diamondback), *C. atrox* (western diamondback), *Crotalus scutulatus* (Mojave rattlesnake), and *Agkistrodon piscivorus* (cottonmouth). The newest US antivenin for the treatment of snake envenomations received FDA approval in May, 2015. Anavip (*Crotalidae* Immune F(ab')<sub>2</sub> (Equine), a *Crotalinae* equine immune F(ab')<sub>2</sub> antivenin indicated for the management of adult and pediatric patients with North American rattlesnake envenomations, was developed by joint efforts of Rare Disease Therapeutics, Inc. and Instituto Bioclon, S.A. De C.V. However, it has not yet been released and is not available for distribution.

Categorizing envenomations based on their severity is not required when considering antivenin therapy. The early indication for “mild to moderate” envenomation has since been expanded to include severe envenomation. As a result, the indications for CroFab therapy are simply the treatment of patients with North American crotaline envenomations. The manufacturer of CroFab has developed a treatment algorithm that may be useful in guiding the physician when treating a victim of crotaline envenomation ([www.crofab.com/documents/CroFab-Treatment\\_Algorithm.pdf](http://www.crofab.com/documents/CroFab-Treatment_Algorithm.pdf)). The administration of CroFab within 6 hours is advised to prevent clinical deterioration and the occurrence of systemic coagulation abnormalities. However, the delayed use of CroFab has been reported with successful correction of significant toxicity incurred after crotaline envenomation.

Antivenin use should proceed simultaneously with supportive therapy (see Box 358-5). CroFab is administered with the goal of achieving *initial control*, which is defined as the reversal or marked attenuation of all effects of venom. This process encompasses 3 general areas: coagulation abnormalities, systemic effects, and local effects (progression of swelling). Box 358-5 outlines the dosing. If *initial control* is not achieved, then the loading dose of 4 to 6 vials should be repeated until the envenomation syndrome is halted. Once initial control has been established, the manufacturer recommends maintenance doses of 2 vials every 6 hours for 3 doses. However, the decision to omit maintenance doses based on the patient’s clinical status, the type of snake, or consultation with a poison center or toxicologist, should be made on a case-by-case basis. Epinephrine, corticosteroids, antihistamines, and airway maintenance equipment should be provided at the bedside. Volume depletion should be aggressively treated before initiating antivenin therapy because of the risk of rapid vasodilatation and third-space fluid loss associated with anaphylaxis. Anaphylaxis associated with antivenin therapy should be treated in the standard fashion.

Preliminary dosing recommendations for Anavip [Crotalidae Immune F(ab')<sub>2</sub> (Equine)] suggest an initial dose of 10 vials, followed by an additional 10 vials as needed to achieve initial control, with a final 4 vials for re-emergence of symptoms as indicated.

Fab antivenin (AV) therapy is associated with clinical improvement in severe crotaline snake envenomations. Based on the results of a multicenter observational case series study of patients who received FabAV at 17 US hospitals from 2002 to 2004, immediate hypersensitivity and serum sickness rates may be less than described in the FabAV prescribing information.

The use of CroFab in children is loosely defined. Children with crotaline envenomations may be more likely to experience serious effects as a result of the larger ratio of venom to serum volume. Any child with a crotaline envenomation that meets the criteria for antivenin therapy should receive the same dosing regimen as adults. Weight-based (ie, per-kilogram) dosing is not appropriate for antivenin neutralization because the dose should reflect venom load, not patient size.

### BOX 358-5 Steps in Using Antivenin

- 1. Prepare to manage anaphylaxis.** An anaphylactic reaction to CroFab is uncommon but has been reported.<sup>a-c</sup> All patients receiving antivenin should be monitored and 2 sites for intravenous access should be considered—1 for the antivenin and 1 for emergency drugs and fluids. Intravenous epinephrine, diphenhydramine, and plasma expanders, as well as cardiorespiratory support, must be readily available.
- 2. Testing for sensitivity—NOT required.** Unlike the previous horse serum–based antivenin, skin testing is not needed for the administration of CroFab. Pretreatment with epinephrine, H<sub>1</sub>- and H<sub>2</sub>-receptor antagonists, or corticosteroids is not routinely recommended unless the patient has a history of hypersensitivity.
- 3. Start the infusion.<sup>d</sup> The dosing is based on estimated venom injected; no dosing adjustment is required for children.** Each vial of CroFab is reconstituted with 18 mL of 0.9% saline. After reconstitution, the entire dose (4–6 vials) is diluted in 250 mL of 0.9% sodium chloride and mixed by swirling gently. Use reconstituted and diluted product within 4 hours. This dose should be infused intravenously over 60 minutes with careful observation for allergic or anaphylactoid reactions.
- 4. Repeat infusion.<sup>d</sup> If initial control is not achieved,** the loading dose of 4 to 6 vials of CroFab should be repeated until initial control of the envenomation syndrome has been achieved. After initial control has been achieved, additional 2-vial doses of CroFab every 6 hours for 3 doses is recommended. Additional 2-vial doses may be necessary, as guided by the patient’s clinical status and consultation with a physician experienced in treating snakebite envenomations or a regional poison control center.

<sup>d</sup>CroFab [package insert]. West Conshohocken, PA: BTG International Inc; 2012.

CroFab use in children ages 14 months to 13 years has been found to be safe and effective.

### Recurrence Phenomena

*Recurrence phenomena* are described as worsening status caused by the return of the venom effect after it has been successfully abated with antivenin. *Local recurrence* indicates the return of swelling after initial control is achieved, and *coagulopathic recurrence* describes the return of thrombocytopenia or hypofibrinogenemia after initial control is achieved. Recurrent coagulopathy has been reported after the use of both ACP and CroFab. With CroFab, the cause of recurrence is probably the clearance of unbound antivenin faster than the absorption and clearance of some venom components. Such may not be the case with

coagulopathic recurrence. All CroFab recipients should be reevaluated at least once during the 5 days after antivenin treatment. The decision to administer additional antivenin in patients who develop delayed coagulopathy must be made on a case-by-case basis. Recent studies indicate that the F(ab')<sub>2</sub> product (Anavip) may be superior at preventing delayed or recurrent coagulation defects versus CroFab, but larger and additional studies are necessary for statistical confirmation of this finding.

An isolated hematologic abnormality after envenomation poses a low risk for significant bleeding, whereas *multicompartment coagulopathies* (critically abnormal INR, activated partial thromboplastin time, fibrinogen, platelets) may represent a risk for bleeding and may warrant additional antivenin consideration. Conservative management for this scenario may be adequate; however, physicians should consult with a clinician experienced in treating crotaline envenomations or with a regional poison control center.

### Antivenin Use in Copperhead Bites

Envenomations by copperheads are not considered to be as serious as rattlesnake or cottonmouth bites. However, clinically significant local effects may occur, suggesting that these bites should be cautiously managed. Furthermore, a retrospective 26-year analysis of annual rates of medical outcomes following copperhead envenomation actually showed significantly *decreased* rates of bites resulting in none or minor effects, with a significant *increase* in rates with moderate outcomes. Those with major outcomes did not significantly change. The victims of copperhead envenomations treated with CroFab had a marked improvement in local tissue effects, but clinical failures and recurrence of local effects also occurred. The use of CroFab in copperhead bites has been shown to halt local tissue effect; however, more data are needed to define the role of CroFab for treatment of copperhead envenomation. The suggested dosing of CroFab in treating a copperhead envenomation is a single loading dose. Additional maintenance doses after initial control did not reduce the incidence of recurrent swelling in one study. After administering the loading dose, the patient should be monitored for progressive swelling, coagulopathy development, and systemic effects. The need for additional antivenin should be evaluated on a case-by-case basis, and a poison control center consultation is advised.

### Prevention and Treatment of Serum Sickness

Delayed reactions to antivenin are thought to be the result of serum sickness-like reactions attributable to immune complexes as a result of an immune response against antivenin proteins. *Serum sickness* is a type-3 hypersensitivity reaction that may occur 7 to 21 days after completion of treatment. Many patients develop serum sickness sometime within 4 weeks after treatment with antivenin, but only a few require hospitalization for this complication. Oral corticosteroids (prednisone) should be prescribed at the first signs (usually urticaria and pruritus) and should be continued for 24 hours after all symptoms have subsided.

The corticosteroid should then be tapered over 72 hours. If necessary, diphenhydramine or hydroxyzine may be added to control pruritus.

### Additional Therapeutic Measures

#### Pain Control

Analgesics should not be overlooked in the management of snakebites. Adequate pain control allows rehabilitation to begin as early as possible to prevent contractures. However, opioid analgesics should be used cautiously if the venom is known to have neurotoxicity (eg, Mojave rattlesnake). Nonsteroidal anti-inflammatory agents should also be used with caution, especially in patients with evidence of coagulopathy.

#### Infection Control

Although snakes have been found to carry a wide variety of bacteria in their mouths (histotoxic *Clostridia*, *Bacteroides*, and many gram-positive and gram-negative aerobes), infection is rare in the absence of severe necrosis, and good wound care is usually sufficient to prevent secondary infections. Systemic and local changes produced by envenomation and the subsequent vascular damage may be difficult to differentiate from infections. If an infection is suspected by clinical or microbiologic evidence, then antibiotic therapy should be instituted. Antibiotic prophylaxis is not currently suggested.

#### Corticosteroids

Corticosteroids should not be used to reduce the inflammation caused by pit viper envenomations. They are not considered a standard of care, and they should not be routinely administered to snakebite victims. However, their use is efficacious in patients who develop serum sickness after antivenin administration.

#### Tetanus Prophylaxis

*Clostridium tetani* are not part of the mouth flora of snakes. Updating the patient's tetanus immunization is the only necessary intervention.

#### Follow-Up Care

The preservation of joint mobility and muscle strength is a goal after pit viper envenomation. Patients who experience full-thickness tissue damage may require referral to a surgeon. Pain control may be needed in the weeks after discharge. If the patient received antivenin therapy, then serum sickness should be discussed and the patient taught how to monitor for this syndrome. Physical or occupational therapy may also be needed to encourage the joint mobilization of the affected extremity. Patients who develop coagulopathy during hospitalization should have follow-up coagulation studies performed on an outpatient basis following discharge.

### CORAL SNAKES

Coral snakes are the members of the Elapidae family that are indigenous to North America. Although their venom can cause a life-threatening paralysis, coral snakes tend to be small, secretive, and mild-mannered unless provoked. Few bites are reported, and death is rare.

### Characteristics

The Eastern coral snake is often mistaken for the non-venomous scarlet king snake because of similar colorful bands encircling the body. The mnemonic *red to yellow, kill a fellow; red to black, venom lack; head of black, step back, Jack!* refers to the color patterns of these snakes. In the United States, all that needs to be remembered is that the coral snakes have black heads (snouts). The poisonous black-snouted snake has broad red and black bands separated by narrow yellow ones; the non-poisonous variety's snout is red, and its broad red bands are separated by narrow yellow ones bounded on each side by black. Despite these distinctions, many people bitten by coral snakes thought they were handling a harmless scarlet king snake.

Unlike pit vipers, coral snakes lack facial pits, are diurnal, and have fixed fangs and nearly round pupils. Their bites may produce superficial scratches or definite fang marks. Their retroverted teeth gnaw or chew on their prey, which makes coral snakes difficult to shake off. Because they must stay attached long enough for their venom to be deposited around their teeth, 50% of coral snake bites are dry. Elapidae venom is primarily neurotoxic; systemic neurologic symptoms are the rule, and local tissue injury is uncommon. Elapidae venom causes paresthesias and paralysis by inhibiting acetylcholine receptors at the neuronal synapse.

### Distribution

Three types of coral snakes are found in the United States: the Eastern coral snake (*Micrurus fulvius*), the Texas coral snake (*Micrurus fulvius tenere*), and the Arizona or Sonoran coral snake (*Micruroides euryxanthus*). Their distribution is shown in Figure 358-3. The bite of the Sonoran coral snake produces no more than local pain and a small amount of nausea.

### Venom Characteristics

*Micrurus* and *Micruroides* venoms have minimal proteolytic activity but contain hyaluronidase and some

phospholipase-A<sub>2</sub>. The venom contains a neurotoxic compound that blocks acetylcholine binding sites at the neuromuscular junction. Despite the relatively simple composition of coral snake venom, its potency should not be underestimated.

### First Aid

Cryotherapy, incision and suction (including the Sawyer extractor), and constricting bands should not be used in any snakebites, including coral snake bites. The Australian pressure mobilization technique has been used, which involves wrapping the entire bitten extremity with a crepe bandage, elastic bandage, or article of clothing as tightly as possible, then splinting it. This approach is different than first aid for pit viper envenomations because, in this setting, differences in venom characteristics mean that local necrosis is not expected.

### Physical Examination: Signs and Symptoms

#### Local

Erythema and local pain from a coral snake bite are transient or absent. Although most patients have evident fang marks, envenomations have been reported that were not associated with apparent fang marks on close examination.

#### Systemic

Systemic manifestations may be delayed for 12 hours and may appear suddenly. They may include bulbar paralysis with ptosis, dysphagia, dysarthria, excessive salivation, paresthesias, euphoria or apprehension, drowsiness, dizziness, weakness, confusion, nausea, vomiting, diaphoresis, muscle tenderness or fasciculations, tremors, altered sensorium, drowsiness, and ophthalmoplegias that cause visual disturbances. These manifestations may be followed by seizures, respiratory paralysis, and pulmonary hemorrhage. Often unclear is which findings are the result of the venom itself and which are the result of hypoxia.

### Laboratory Studies

Coral snake bites do not mandate routine laboratory screening. Transcutaneous pulse oximetry, arterial blood gases, or both, should be assessed if respiratory insufficiency is suspected.

### Supportive Therapy

Elective intubation before impending respiratory paralysis tends to prevent aspiration pneumonia. Elective intubation should be performed if any signs of bulbar paralysis develop. The patient should receive cardiac and pulse oximetry monitoring (if not intubated), and intravenous access should be established.

All victims of potential coral snake envenomation should be admitted to an intensive care unit for close monitoring for a minimum of 12 hours, because the effects of envenomation may develop precipitously hours after a bite and are not easily reversed once they occur.

### Use of Antivenin

Historically, antivenin effective against Eastern and Texas coral snake venom (*M. fulvius*), produced by Pfizer, Inc./Wyeth Pharmaceuticals, was used if a

**Figure 358-3** Coral snake distribution in North America. (From Quan D. North American poisonous bites and stings. Crit Care Clin. 2012;28:633–659, with permission from Elsevier.)

patient had been bitten by a coral snake (positively identified) or if any signs or symptoms of envenomation developed. These guidelines were based on the judgment that the risks of intravenous hyperimmune horse serum are offset by the potential prevention of respiratory paralysis, which may occur if therapy is not immediately administered. At the time of this chapter revision, Pfizer/Wyeth Pharmaceuticals, who is the sole producer of coral snake antivenin, will no longer manufacture it. *When present stocks are depleted, there will be no FDA-approved antidote for coral snake envenomation.* Currently, hospital pharmacists can order replacement supplies of North American Coral Snake Antivenin (*Micrurus fulvius*), Lot #4030024 by calling Customer Service at 1-800-666-7248. Though this lot is labeled with an expiration date of February, 2007, the FDA again extended the expiration date from April 30, 2015 to April 30, 2016.

Additionally, there is a trial in Florida currently underway evaluating a novel antivenin, INA2013. Contact the Florida Poison Information Center-Tampa at 813-844-7044 for more information about this clinical trial.

If antivenin is available and the decision to administer it is made, skin testing may be performed but yields many false-negative findings and is of little benefit in making therapeutic decisions. Three to 5 vials of antivenin are mixed in 250 to 500 mL of normal saline, and 1 to 2 mL is given intravenously over 3 to 5 minutes. The medical team must be prepared for anaphylaxis and have necessary drugs and equipment at bedside. If the patient does not exhibit any signs of an allergic reaction, then the remainder of the solution is infused slowly as tolerated. An additional 3 to 5 vials of antivenin-saline mixture may need to be infused if the patient's signs and symptoms do not abate or worsen. Rarely are more than 10 vials of antivenin required for victims of coral snake envenomations.

### Additional Therapeutic Measures

Prophylaxis for infection and tetanus are the same as for pit viper bites. Additional measures may become necessary if aspiration pneumonia develops. Patients should be aware that muscular weakness may persist for 3 to 6 weeks.

## NONINDIGENOUS SNAKES

The variety of imported snakes is too great to detail in this text. If a bite from an exotic species is suspected, then the suggested approach includes local wound care, supportive care, and consultation with experts at a regional poison control center.

### WHEN TO REFER

- Hymenoptera: systemic reactions to be evaluated for immunotherapy
- Arachnids
  - *Loxosceles*: surgical intervention necessary for wound care
  - *Latrodectus*: before administration of antivenin therapy
- Snakes
  - *Tarantulas*: hairs in eyes that are not easily removed
  - *Scorpions*: considered use of antivenin
  - *Pit vipers*
    - Considered use of antivenin
    - Surgical intervention necessary for wound care
  - *Coral snakes*: anticipated need for airway control or intensive care unit monitoring

### WHEN TO ADMIT

- Hymenoptera: severe systemic allergic reactions or severe systemic reactions caused by massive envenomation
- Arachnids
  - *Loxosceles*
    - Secondary infection requiring intravenous antibiotics
    - Inability to provide adequate wound care at home
    - Presence of systemic symptoms, as severe hemolysis can occur quickly
  - *Latrodectus*
    - Severe systemic symptoms
    - After use of antivenin
  - *Tarantulas*
    - Significant comorbidity
    - Inability to tolerate oral fluids
  - *Scorpions*
    - Cardiac or neurologic toxicity
    - Severe systemic signs or symptoms
- Snakes
  - *Pit vipers*: symptomatic envenomation
  - *Coral snakes*: chance of envenomation

## Chapter 359

# ESOPHAGEAL CAUSTIC INJURY

Robert L. Ricca, MD; George T. Drugas, MD

Caustic injury of the esophagus is a major, although preventable, pediatric public health concern. Despite an increasing public awareness and prevention strategies, unintentional and intentional ingestion of agents remains a significant cause of morbidity and mortality in this country. Corrosive esophageal injuries continue to occur in the United States in spite of federal legislation mandating preventive packaging and labeling, injury prevention programs designed for children and parents, and laws restricting the potency and availability of caustic substances. Most exposures still occur in young children. Over 35% of all toxic ingestions occurred in children younger than 3 years and nearly 50% occurred in children younger than 6 years in 2013. Household cleaning agents are still among the top 5 substances ingested by children, comprising 7.6% of ingestions by patients in 2013 (down from 9.7% in 2003). In children younger than 5 years, these agents account for 10.4% of all toxic agents ingested.

Boys continue to comprise most patients younger than 13 years. In children over 13 years, when intentional ingestion becomes more prevalent, there is a preponderance of girls. Despite this seemingly large number of exposures, less than 9% of all fatalities from human ingestion occurred in the pediatric (<19 years) population in 2013. Twenty percent of caustic ingestions result in some form of esophageal injury, and, although death from caustic ingestion is rare (3.2% of all pediatric deaths from ingestion in 2010 due to household cleaning agents), the morbidity can be devastating. Medical treatment for corrosive esophageal injury is reasonably well established, but best surgical management remains debatable and can entail rather complex procedures with significant

long-term functional, cosmetic, and psychological sequelae. A concerning development in the changing spectrum of esophageal ingestion injury is the increase in household use and ingestion of lithium battery cells. There has been a 6.7-fold increase in the percentage of button battery ingestions with major or fatal outcomes from 1985 to 2009, according to the National Poison Data System.

### PATHOPHYSIOLOGIC FEATURES

The extent of injury after a caustic ingestion depends on the type of agent (acid versus alkaline), whether the substance was liquid or solid, the concentration, the volume ingested, and the duration of contact between the substance and the mucosal lining. Additionally, agents with a pH under 2 or over 12 are extremely corrosive. Solid or powder substances adhere to the oropharynx, maximally burning focally with sparing of the esophagus. Liquids rapidly reach the esophagus and stomach, causing greatest damage to these more distal sites. Alkaline substances are more available than acidic substances in Western countries and are involved in most corrosive ingestions. Household bleaches, drain cleaners, automatic dishwasher detergents, anhydrous Benedict's reagent tablets, and denture cleaning tablets are common alkaline household products. Common household acids are toilet bowl cleaners, rust removers, battery fluids, and swimming pool cleaners (Table 359-1).

Ingestion of liquid laundry detergents and dishwasher solutions found in the home usually results in mild esophageal injury that heals without complication. Special consideration should be given to the recent availability of alternative packaging of detergent in pod packets. These packets potentially result in more extensive injury because of higher concentration of detergent despite the smaller volume. Household bleaches have rarely been associated with severe esophageal injury because of their low concentration of sodium hypochlorite. Strong alkalis cause liquefaction necrosis that allows penetration of the corrosive agent transmurally through the esophagus and into adjacent mediastinal tissues. Heat production and small-vessel thrombosis resulting from the reaction compound the initial damage. The ensuing inflammatory reaction can result in gangrene, perforation, mediastinitis, fibrosis, or severe contracture of the esophagus. Lye (sodium hydroxide) is the lay term for the alkaline agent found in most cleaning substances. Liquid lye is the most common cause of esophageal caustic injury and is associated with the greatest morbidity. Lye is odorless, tasteless, and viscous; these characteristics allow it to be easily ingested by children and in massive volumes by suicidal teens and adults. Lye's high viscosity retards transit through the esophagus, making it particularly injurious; tissue injury is rapid in the first few minutes but can persist for hours. Solid alkalis, such as anhydrous Benedict's reagent tablets and batteries, tend to lodge during transit, resulting in focal burns, pressure necrosis, and subsequent perforations at their point of impaction.

Lesions caused by lye injury occur in 3 phases. The acute *necrotic* phase usually lasts 24 to 96 hours after ingestion. An intense inflammatory reaction surrounds

**Table 359-1 Household Agents Causing Caustic Exposures**

CHEMICAL	PRODUCT
<b>ACIDIC</b>	
Hydrochloric acid	Swimming pool cleaners, toilet bowl cleaners, metal cleaners
Hydrofluoric acid	Rust removers
Sulfuric acid	Automotive batteries, drain cleaners
<b>ALKALINE</b>	
Ammonia	Toilet bowl cleaners, hair dyes, floor strippers, glass cleaners
Sodium hydroxide	Anhydrous Benedict's reagent tablets, detergents, laundry powders, paint removers, drain cleaners, button batteries, oven cleaners
Sodium borates, carbonates, phosphates	Detergents, electric dishwasher detergents, water softeners
Sodium hypochlorite	Bleaches, household cleaners, mildew remover

nonviable tissue. During the second *ulceration and granulation* phase 3 to 5 days after injury, superficial necrotic tissue sloughs and is replaced by an ulcerated and inflamed granulation bed. The healing tissue lacks collagen deposition and has very little tensile strength. Although perforation can occur at any point during the first 2 weeks after injury, during this phase (lasting 10–12 days), the esophagus is most vulnerable. The third phase of *scarring and cicatrization* begins during the third week after injury. In this period, contracture of the wound may lead to stricture formation and alteration of lower esophageal sphincter pressure, leading to gastroesophageal reflux.

Batteries can cause injury to the esophagus through multiple mechanisms. Aside from pressure necrosis, batteries can contain mercuric oxide or disperse electrical charge at the negative pole, causing mucosal burn as well as injury to adjacent structures. Additionally, caustic injury may occur from leakage of alkaline material (hydroxide). The most injurious tend to be lithium hydroxide batteries and larger cell batteries over 20 mm in diameter. Even spent cells have sufficient residual voltage and capacitance to generate an external current, produce hydroxide, and cause disastrous outcomes. Rapid identification through radiographic imaging and immediate removal is recommended to mitigate injury. Short exposure time has been shown to still produce severe injury. Exposures of 2 to 3 hours have resulted in major morbidity, including stricture, vocal cord paralysis, requirement for tracheostomy, tracheoesophageal fistula, or potentially life-threatening hemorrhage through aortoesophageal fistula.

Strong acids, unlike alkalis, have an offensive odor and bitter taste that usually results in rapid expectoration after accidental ingestion. Because acids exhibit rapid esophageal transit, they were previously thought to cause more damage to the stomach or intestine; however, recent studies have revealed that acids also cause extensive esophageal injury. Acids cause coagulation necrosis, resulting in superficial eschar formation, which may, in part, limit penetration into deeper tissues. However, a recent retrospective review of more than 200 children with caustic ingestion saw no differences in the incidence of stricture formation after acid or alkali ingestion. Acids and alkalis alike

can induce pylorospasm, resulting in pooling of the caustic agent in the gastric antrum, with extensive damage to this area.

## DIAGNOSIS AND INITIAL MANAGEMENT

After caustic ingestion, symptoms can consist of searing or burning pain of the mouth and lips, drooling or hypersalivation, and difficulty with swallowing. Worth emphasizing is that the absence of pain does not exclude significant injury. Epiglottic or vocal cord edema may result in stridor, dysphonia, or aphonia. Substernal or back pain usually results from esophageal disruption and mediastinitis. Acute epigastric pain may indicate gastric perforation. The presence of fever is strongly correlated with significant esophageal injury. The primary care physician must recognize that the absence of oral burns does not exclude an esophageal burn injury and that 20% to 45% of patients with esophageal burns have no evidence of oral burns. Conversely, oropharyngeal damage does not reliably indicate esophageal involvement; 70% of persons with oropharyngeal injuries do not have esophageal lesions. Bleeding can occur and results from mucosal sloughing, with persistent ooze from the exposed submucosa or muscularis. Life-threatening hematemesis from the development of an aortoesophageal fistula is, however, a rare event. Tracheoesophageal fistula is another rare complication seen with injury to the anterior wall of the esophagus. No single symptom, sign, or combination has been found to predict accurately the degree of esophageal injury after corrosive ingestion.

Every attempt should be made to identify the agent ingested. In the case of young children, parents are usually aware of the offending agent and often bring the container to the emergency department. With suicidal intent, the caustic agent may be unknown. Stridor or aphonia indicate laryngoepiglottic injury and may require urgent orotracheal intubation for airway protection. Occasionally, severe laryngeal destruction necessitates emergency cricothyroidotomy or tracheostomy. Adequate vascular access should be obtained to allow for correction of hypovolemia or hypotension. A chest radiograph may identify concomitant

**Figure 359-1** Esophageal caustic injury from battery ingestion.

aspiration, subcutaneous cervical emphysema, or pneumomediastinum corroborating perforation. A lateral chest radiograph is essential to help distinguish a coin from a battery, the latter prompting emergent endoscopic retrieval. Additional information can be obtained by determining the narrow portion of the battery, which corresponds to the negative charge and adjacent area of necrosis. This can assist with localization of the injury during subsequent endoscopic evaluation. Gastric lavage and emetics should be avoided because of the risk of re-exposing the esophagus to the ingested corrosive agent and because of the threat of aspiration. Any attempt to neutralize an ingested caustic agent poses an additional danger because the resultant exothermic reaction often exacerbates the primary burn injury. Activated charcoal is ineffective and obscures visualization with endoscopy, and is therefore not recommended. Gastric lavage is contraindicated because it may result in propagation of injury beyond the level of the pylorus. Placement of a nasogastric tube should be deferred because of risk of esophageal perforation.

Only after the patient is stabilized should the airway and gastrointestinal tract be inspected. The initial examination should include laryngoscopy. Evidence of a supraglottic or epiglottic burn indicates a risk for airway obstruction and requires endotracheal intubation. Presence of a third-degree burn to the hypopharynx precludes advancement of the endoscope beyond that level. Once the upper airway integrity is confirmed, endoscopy should be performed, even in the absence of oropharyngeal burns, to establish the extent of injury (see Figure 359-1). More than 50% of patients of caustic ingestion will have no evidence of damage to the oropharynx or proximal gastrointestinal tract. A thorough examination, however,

### BOX 359-1 Grading of Caustic Esophageal Burns

- Grade 0: normal
- Grade I: mucosal hyperemia and edema
- Grade IIa: mucosal hemorrhage, exudate, superficial ulceration, sloughing, and pseudomembrane formation
- Grade IIb: IIa plus deep discrete or circumferential ulcerations
- Grade IIIa: deep ulcerations and necrosis, massive hemorrhage, obliteration of the lumen, charring, and perforation
- Grade IIIb: extensive necrosis

Modified from Zargar SA, Kochhar R, Mehta S, et al. *Gastrointest Endosc.* 1991;37(2):165–169. Copyright © 1991, Elsevier, with permission.

is warranted, because many will have extensive esophageal damage in the absence of oropharyngeal lesions. Flexible, rather than rigid, esophagoscopy is preferred to minimize the risk of iatrogenic perforation. Most endoscopists, fearing perforation, will advance the scope only to the level at which maximal injury is encountered; others advocate full examination of the stomach and, if possible, the duodenum. The degree of injury can be graded similarly to that of thermal skin burns and holds similar prognostic implications (Box 359-1). Accurate assessment by an experienced endoscopist can guide therapy for severe injury and avoid unnecessary treatment for patients with mild or no injury. Endoscopy only allows examination of superficial mucosa, which makes differentiating between grade-IIb and grade-III lesions difficult. Circumferential burns limit full visualization with endoscopy, and contrast radiography may be required for identification of grade-III injuries. Contrast radiography uses water-soluble contrast followed by thin barium (Figure 359-2). Batteries should be removed from the esophagus emergently, typically by endoscopy, preferably within 2 hours of ingestion. Endoscopy will additionally allow further identification of the negative pole relative to the surface of the esophagus. Batteries that have passed into the stomach, unless ingested with a magnet, can be allowed to pass with expectant management.

### MEDICAL MANAGEMENT

Therapy for a caustic injury to the esophagus depends on the grade assigned at endoscopy. Children with no injury or grade-I injuries are usually admitted and observed for 24 to 48 hours. Children with more severe injuries are admitted to the pediatric intensive care unit for monitoring and management. As with any patient, close attention to the ABCs (airway, breathing, and circulation) is of paramount importance. Aside from the risk for perforation, nasogastric tube placement is not indicated routinely because it may be associated with subsequent stricture formation.

Initially, patients with more severe or extensive injuries may ingest nothing orally and require proper

**Figure 359-2** Esophagram demonstrating long-segment esophageal stricture after lye ingestion in a 2-year-old girl.

fluid resuscitation, nutritional support through total parenteral nutrition, and pain management. After disruption of the mucosal barrier by caustic ingestion, bacterial translocation and secondary bacterial invasion are likely events. This rationale is offered for early institution of prophylactic antibiotic therapy; however, controlled trials do not support antibiotic use, and therefore most experts no longer advocate empirical therapy. Vigilance for mediastinitis or systemic infection must be maintained and appropriate antimicrobials reserved for any evidence of local or systemic infection. For grade-II and grade-III injuries, parenteral nutrition is begun and oral feedings are withheld until the dysphagia of the initial phase has regressed and no evidence exists of clinical or radiographic deterioration.

Proton pump inhibitors should be prescribed, because loss of lower esophageal sphincter tone occurs secondary to corrosive esophageal injury, and acid reflux can exacerbate the underlying injury and accelerate stricture formation. The use of steroids to limit fibrosis after caustic injury has debatable efficacy in humans. Most studies demonstrate a lack of proven benefit, and the potential side effects of steroids argue against routine use. Strictures after grade-I and grade-IIa injuries are rare, and follow-up contrast esophagography is unnecessary. After grade-IIb and grade-III injuries, a barium esophagram for the early detection of stricture development is performed 2 to 4 weeks later. Multiple animal studies with a variety of agents (heparin, epidermal growth factor, caffeic acid phenethyl ester) have

demonstrated varying degrees of success in ameliorating stricture formation, but none of these agents have been studied in humans.

## SURGICAL INTERVENTIONS

Initial therapy begins with endoscopy, which can rapidly ascertain the extent of injury as well as the possible need for immediate surgical therapy, including esophagectomy. If immediate surgical management is not needed and medical management is required, then repeat endoscopy is used for those patients at an increased risk for developing stricture (higher-grade injuries) or those patients whose symptoms arouse concern for stricture development. Initial treatment of esophageal stricture following caustic ingestion is through repeat endoscopy and subsequent dilation of the stricture. While initial studies looking at esophageal dilation did not show promising results, more recent studies have been more optimistic. Primary treatment with esophageal dilation offers a satisfactory outcome for most otherwise healthy children with grade-IIa injuries. However, repeated dilation is rarely successful for the most severe corrosive strictures, and early surgical resection is associated with a better outcome. Esophageal dilation to prevent adhesion formation in the injured segment, intraluminal stenting, and prolonged esophageal rest (maintenance of nothing-by-mouth status; total parenteral nutrition) have all been proposed for prophylaxis against stricture formation, but none has demonstrated a proven benefit. Because the risk of perforation is highest in the first weeks after injury, most experts advocate waiting 6 weeks before initiating dilation therapy. Dilation can be accomplished by 2 methods—passing graded bougies over endoscopically or radiographically placed guide wires (pulsion dilation), or using endoscopically or radiographically controlled balloon dilation (radial dilation). Dilation with bougies passed endoscopically is difficult with tortuous or complicated strictures and warrants fluoroscopic guidance. Dilation is typically performed every other week with the goal of dilating the stricture to 18 mm, which is the required diameter for normal swallowing. Typically, 3 or more dilations are required to achieve this goal. Early or aggressive dilation may result in further injury to the esophagus. The reported incidence of rupture resulting from dilation ranges from 17% to 32%. Esophageal rupture is a potentially fatal complication of dilation and warrants immediate surgical repair. In addition to the risk of perforation, serial dilations are also complicated by dysphagia between treatments, which may precipitate pulmonary aspiration. An adequate lumen is usually attained within 6 months to 1 year, with progressively longer intervals between dilations. Consider esophageal replacement if dilation is ineffective beyond 1 year.

Esophageal stenting may be used alone or in combination with dilation to treat esophageal stricture. A recent study looking at 79 children using a custom-made stent in addition to acid blockade and steroids showed promise in preventing stricture formation. Seventy of the 79 children treated were able to be managed with stenting alone, thereby avoiding further surgical therapy. Many of

these children still required esophageal dilation following stent removal but were able to avoid the morbidity and mortality of major esophageal surgery. A second, smaller study looked at the use of available nitinol stents in 8 children with esophageal stricture. Short, 6-month follow-up revealed improvement in dysphagia scores and tolerance of oral feedings, and only 2 children required further esophageal dilation. Severe complications, including stent migration and erosion of the stent, have been reported in the literature. Further improvements in stent design and deployability continue to make this an attractive alternative in the armamentarium of surgical management.

For children who present with severe caustic injuries, early surgical intervention is vital and can be lifesaving. Full and immediate resection of devitalized tissue is necessary to prevent expansion of the corrosive injury. Delay in diagnosis of an esophageal perforation can be fatal, and a high index of suspicion in grade-II and grade-III injuries must be maintained. The presence of peritonitis, pneumoperitoneum, or clinical deterioration, as evidenced by refractory acidosis, neurologic decline, or coagulopathy, requires immediate surgical intervention. Complete surgical exposure of the foregut—esophagus, stomach, and duodenum—is necessary to assess the extent of the damage and allow for possible resection. Full-thickness injury to the stomach or duodenum invariably predicts severe esophageal injury and is an indication for complete esophagogastrectomy. Full-thickness circumferential injury to the esophagus carries 20% mortality, mandating surgical resection. Conservative management, including later esophageal dilation, may be considered for short segments of full-thickness esophageal mucosal damage. If any question persists after the initial exploration, then a second-look operation (often within 24 hours) is required.

Surgical management is required for the most severe corrosive injuries and for intractable esophageal strictures. The surgical options include bypass with placement of an esophageal substitute or resection, or both, or esophagoplasty (Figure 359-3). Bypass with complete esophageal resection is the preferred approach, because retained proximal esophagus may distend and form a mucocele or abscess; distal esophagus may develop reflux esophagitis, ulceration, and hemorrhage; and retained esophagus carries increased risk for malignant transformation. Resection, however, is not without risk; the extensive dissection necessary to remove the damaged esophagus can result in significant morbidity. Colonic interposition, gastric advancement, gastric tube esophagoplasty, and jejunal interposition are accepted procedures to replace the injured esophagus. Esophagoplasty with a colonic patch over less extensive but persistent strictures has also been used in the management of focal strictures. Decisions regarding surgical management are based on patient age, general health, severity and extent of stricture, and risk of long-term complications.

## DELAYED COMPLICATIONS

Long-term complications of corrosive ingestions include stricture formation (see Medical Management),

**Figure 359-3** Colonic interposition in a child 6 months after esophageal injury. This is the same child in Figure 359-1.

gastric outlet obstruction, and esophageal carcinoma. Not surprisingly, the long-term morbidity after corrosive esophageal ingestion correlates with the grade of injury. Gastric outlet obstruction occurs in approximately 9% of corrosive ingestions and is characterized by early satiety and weight loss. The obstruction can occur years after the initial injury and follows acid or alkaline ingestions with equal frequency. The treatment of gastric outlet obstruction is surgical, and balloon dilation of the pylorus, pyloroplasty, and Billroth I reconstruction are all effective. The type of operation performed depends on findings at laparotomy and surgeon preference.

For patients in whom the native esophagus is retained, the risk of post-corrosive esophageal carcinoma is estimated to be 1,000- to 3,000-fold higher than the incidence for esophageal cancer in the general population, and up to 3% of patients with esophageal carcinoma have a history of corrosive ingestion. These squamous cell carcinomas usually originate in the mid-esophagus. Local dissemination occurs infrequently, so the potential for curative resection is slightly improved over primary esophageal malignancies. The interval between burn injury and the development of carcinoma ranges from 10 to 70 years, with a mean of 50 years. Long-term follow-up of children who have grade-II and grade-III burns is warranted, regardless of their symptoms. Esophagography and surveillance esophagoscopy should be performed one or two times per year.

## Chapter 360 HEAD INJURIES

Prashant Mahajan, MD, MPH, MBA; Sean Indra, MD

Traumatic brain injury (TBI) is the leading cause of death and disability in children. It is estimated that half a million children in the United States experience TBI annually, and TBI accounts for 435,000 emergency department (ED) visits, 60,000 hospitalizations, and 7,400 deaths each year. The financial burden in terms of medical costs and lost productivity has been estimated at \$100 billion per year.

The epidemiology of TBI varies with gender (boys are twice as likely as girls to suffer from TBI) and age. In infants and school-aged children, the major mechanisms of injury include falls from height and from standing, whereas assault, sports injuries, and motor vehicle collisions account for most TBIs in adolescents. For all ages combined, falls are the most common cause of head trauma, but vehicular collisions are the leading cause of TBI that results in serious injury. In most vehicular collisions, the child is a pedestrian. Most children who are hit by a vehicle and have TBI are not supervised by an adult at the time of the accident.

### PATHOPHYSIOLOGIC FEATURES

The brain is covered by 3 layers of meningeal tissue (pia mater, arachnoid mater, and dura mater), followed by the skull bones (calvarium) and scalp, which has a strong layer of tissue (galea aponeurotica). The brain does not adhere to the skull and is able to move freely within it, cushioned to some extent by the cerebrospinal fluid in which it bathes. *Primary brain injury* refers to the neural injury caused by the traumatic insult and presents in the form of contusions, intracranial bleeding, fractures, or diffuse axonal injuries. *Secondary brain injury* refers to the subsequent injury to the neural tissue after a trauma has occurred. It has

numerous causes, including hypoxia, hypoperfusion, excitotoxic damage, free radical damage, or metabolic derangements. Sometimes the damage caused by secondary brain injury is more devastating than that from the primary insult. The most important cause of secondary brain injury is brain ischemia resulting from inadequate cerebral blood flow. Adequate cerebral blood flow depends on the cerebral perfusion pressure, which is the difference between mean arterial pressure and intracranial pressure (ICP). Normally the cerebral perfusion pressure fluctuates inside a narrow range, the result of cerebral autoregulation. However, when this control mechanism is lost because of brain injury and secondary brain tissue damage, an increase in intracranial volume (mainly the result of intracranial hemorrhage or cerebral edema) will lead to a disproportionate increase in ICP. This increase further accentuates neuronal damage by reducing cerebral blood flow. An increase in ICP may lead to cerebral herniation syndromes. These syndromes are characterized by worsening of sensorium, pupillary changes, widening pulse pressure, and the Cushing triad, which includes hypertension, bradycardia, and irregular respirations.

### TYPES OF TRAUMATIC BRAIN INJURY

#### Concussion

*Concussion* or *mild TBI* is defined as brain injury caused by a biomechanical force resulting in alterations in neurologic function. The typical spectrum of symptoms involves changes in memory and orientation and may include loss of consciousness. It is estimated that annually, 3.8 million people suffer from concussions related to sports or recreational activities. This figure is likely a conservative estimate because the number of children participating in organized sports has increased from 40 million in 2000 to 60 million in 2008.

Sports-related concussion is a relatively frequent injury in the United States and occurs commonly in athletes who play American football, ice hockey, soccer, basketball, baseball, and softball. The diagnosis of concussion comprises a constellation of symptoms including physical (headache, nausea), cognitive (feeling mentally “foggy” or slowed down), emotional (irritability, sadness), and sleep (drowsiness, sleeping more/less than usual) changes. On-field evaluation of players with suspected concussions is critical and should be performed by a physician or other licensed clinician. A number of sideline assessment tools are available, such as the Sports Concussion Assessment Tool V.3 (SCAT3), to aid in identification of mild TBI, but the evidence to identify the best diagnostic measures is insufficient. Routine imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is not currently recommended. Those who have been determined to have concussion should be serially monitored on the sideline and not be allowed to return to play on the day of injury; they should have prompt follow-up with their primary physician.

#### Skull Fractures

Skull fractures occur in approximately 2 per 1,000 infants and 0.5 to 1 per 1,000 older children and adolescents. The most common bone to fracture is the parietal

bone. Most fractures can be diagnosed with plain-film radiography or CT with bone windows. Linear skull fractures often require no intervention, although most pediatricians would admit these children for a period of observation. Depressed skull fractures are often associated with underlying brain abnormalities and may require surgical interventions. Basilar skull fractures are often associated with cerebrospinal fluid leakage and cranial nerve damage. These fractures require pediatric neurosurgical intervention and should ideally be managed at tertiary care pediatric trauma centers.

### Parenchymal Injuries

*Cerebral contusions* are bruises of the cerebral cortex that can occur as a result of direct injury (coup injury) or at the opposite point where the relatively mobile brain strikes the bone on the other side (contrecoup injury). Clinical manifestations vary, but patients often exhibit some alteration in consciousness, focal seizures, or focal neurologic findings (eg, cortical blindness in cases of occipital lobe injury). Most cases are diagnosed with CT, and management depends on the extent of injury. Patients may need to be observed with ICP monitoring, and some may require craniotomy for drainage of intracerebral hematomas.

### Diffuse Axonal Injury

*Diffuse axonal injury* is often seen after an acceleration-deceleration or rotational mechanism (commonly called *whiplash*); the damage is at the gray matter–white matter junction. Most children experience changes in sensorium, and some studies have reported that about 82% develop coma. Although some changes with diffuse axonal injury may be seen on CT,

MRI is often diagnostic. Most patients with diffuse axonal injury will need hospitalization along with monitoring of ICP in the intensive care unit.

### Intracranial Hematoma

Although hematomas can occur anywhere in the intracranial space, the 2 most common types are epidural and subdural (Table 360-1).

### INITIAL CARE

Most physicians have little trouble identifying patients who require intensive care at a regional medical center. More difficult is deciding whether to admit the less severely injured child to the hospital for observation. Decisions regarding the hospitalization of less severely injured patients must be made on a case-by-case basis.

The improved prognosis for survival and neurologic recovery after a severe head injury in a child compared with an adult dictates that the physician providing emergency care make every effort to adequately and appropriately resuscitate the child who has a severe head injury. The basic ABCs of resuscitation (airway, breathing, and circulation) should be addressed first. Maintaining normal oxygenation is imperative, as was aptly stated by Haldane in 1919: “Anoxia not only stops the machine but wrecks the machinery.” In addition, ischemia, increased ICP, and uncontrolled seizures may cause further brain injury. The correction of hypotension, hypothermia, hypocapnia, and acidosis is imperative in reducing overall mortality and length of stay in the intensive care unit.

Patients with severe TBI often require assisted ventilation to maintain ICP and benefit from rapid sequence induction for airway management. In the

**Table 360-1** Differences Between Epidural and Subdural Hematomas

CHARACTERISTIC	EPIDURAL HEMATOMA	SUBDURAL HEMATOMA
Mechanism	Direct trauma leads to bleeding from the middle meningeal artery or shearing of epidural veins.	Shaking (acceleration-deceleration) injury leading to tearing of bridging veins in the subdural space. In young children, this may result from child abuse.
Clinical manifestations	Lucid interval—symptom-free interval between time of injury and time of manifestation can be seen in <50% of cases. Patients run the gamut from asymptomatic to those who exhibit focal seizures and coma.	Lucid interval unlikely. Many children exhibit coma, seizures, or evidence of chronic changes (tense anterior fontanel, macrocephaly).
Investigations	CT is diagnostic for a lenticular lesion, which is often seen without an overlying fracture.	CT scans reveal blood collection as a hyperdense crescentic collection along the cerebral hemisphere. In cases of child abuse, hemorrhage of different ages can be seen with changes suggestive of hydrocephalus.
Management	Most small bleeds resolve with supportive therapy; however, if clinically indicated, treatment may involve a craniotomy with drainage of hematoma and repair of the ruptured blood vessel.	Management will vary depending on extent of bleeding, and in some cases ICP monitoring with expectant observation may be the only therapy; intracranial evacuation of blood clot may be the therapy of choice for some cases.
Prognosis	Excellent after initial insult is adequately treated.	Poor with high mortality and high morbidity (sequelae).

CT, Computed tomography; ICP, intracranial pressure.

severely injured patient, the airway requires intubation to ensure adequate ventilation and reduce the chance of developing increased ICP. Close attention to blood pressure is necessary because sedatives may cause hypotension. In the past, prolonged hyperventilation was suggested for patients with acute severe head injury. Although hyperventilation constricts intracranial blood vessels and lowers ICP, concerns exist that it may decrease cerebral perfusion. Meticulous attention must be paid to carbon dioxide pressure in the arterial blood to prevent hypercapnia at all costs, and can be accomplished through the use of end-tidal capnography. Mild hyperventilation to maintain partial pressure of carbon dioxide at 30 to 35 mm Hg is recommended and may be useful in an emergency situation in which the patient's condition deteriorates acutely because of increased ICP.

### History

When taking a history, the possibility of abuse must be kept in mind. Abuse should be considered when families deny any trauma or when they provide a history of minor trauma and the child has life-threatening, severe, or multiorgan injury. For example, children rarely experience a serious injury when they fall out of bed, so such a history, when given as the cause of severe injury, may be an indication of child abuse. Loss of consciousness, seizures, amnesia for the circumstances surrounding the injury, and focal neurologic deficits are indicators of more severe head trauma. Vomiting and headache are common symptoms after head trauma, and their presence, if not persistent or severe, is not particularly ominous or suggestive of a specific pathologic finding. Persistent clouding of consciousness is the most reliable sign of a significant brain injury. In addition, the duration of posttraumatic amnesia, defined as an inability to generate new memories after head injury, correlates positively with the severity of the injury.

### Physical Examination

Examination of the patient should begin with assessment of mental status and assignment of a Glasgow Coma Scale (GCS) score. Neurologic examination should proceed with assessment of the cranial nerves. Particular attention needs to be given to pupillary responses and symmetry, funduscopic examination (to rule out papilledema or hemorrhage), eye movements (to assess for dysconjugate gaze), asymmetries of facial sensation or movement, tongue movement, and gag reflex. As a sensory screening examination, symmetrical responses to pain in all 4 limbs should be determined. Symmetry of muscle tone and movement and of the deep tendon reflexes and plantar responses needs to be determined, as should the alert, cooperative child's ability to manipulate small objects. The child's gait and posture also need to be assessed. The general physical examination should focus on the presence of injury to other body systems and on seeking evidence of physical neglect or abuse.

### Neurologic Evaluation

A more detailed neurologic examination should be performed only when adequacy of the airway, breathing, and circulation are ensured. The GCS, or

a modified GCS for children and infants, can be used to evaluate mental status and is valuable in assessing level of consciousness and in following the child's progress (Table 360-2). The scale is based on the patient's response in 3 areas: motor response, verbal response, and eye-opening response. Severe head injury may be defined as that resulting in a GCS score of less than 9, whereas moderate head injury is associated with a score of 9 to 12. A score of 13 to 15 indicates a mild head injury.

Motor response is evaluated by noting symmetry of tone, movement, and reflexes. Cranial nerve examination may reveal signs of focal injury to the brainstem. Pupil size, symmetry, and reactivity should be noted carefully, and the fundus should be examined for signs of papilledema. Retinal hemorrhages suggest the possibility of abusive head trauma. Pontine and midbrain function may be assessed by examining oculovestibular reflexes. In the unconscious child, the head should be rotated briskly from side to side after making certain that the cervical spine has not been injured. Normally, when the head moves to the right, the eyes move to the left, and vice versa. Loss of these reflex eye movements in a comatose patient suggests an injury to the midbrain or pons. Alternatively, if the tympanic membranes are intact, then ice-water caloric responses should be elicited. With the child's head elevated to 30 degrees, 120 mL of ice water is infused alternately into each ear canal. The eyes should turn toward the irrigated ear. If they do not, then a brainstem injury is likely. The quality and symmetry of the grimace evoked by painful stimulation of the face should be observed. Next, the corneal reflex should be tested, and failure to react by blinking is consistent with pontine injury or deep coma. All the tests should be performed, even if 1 of them is positive. Function is evaluated by assessing the child's gag reflex and tongue movement. The child's craniospinal axis should be examined in concert with the neurologic assessment for signs of trauma. Swelling and bony depression of the skull suggest an underlying fracture. Ecchymoses behind the ear (the Battle sign) or around the orbits (raccoon sign), cerebrospinal fluid rhinorrhea, otorrhea, or hemotympanum suggest a basilar skull fracture. Basilar fractures or scalp lacerations overlying fractures are important to detect because they serve as portals of entry for bacteria into the subarachnoid space and may cause meningitis. Because of the risk for meningitis with any of the prior clinical findings, serial neurologic examinations are critical to provide ongoing monitoring.

### Imaging Studies

The following 5 clinical findings identify 99% of all children with TBI documented with CT and 100% of those who require neurosurgery: abnormal mental status, clinical signs of skull fracture, scalp hematoma, history of headache, and vomiting. A clinical decision rule excludes TBI that needs neurosurgical intervention (negative predictive value of 100%) when none of these 5 clinical variables is present. Use of this rule will reduce unnecessary exposure to CT radiation by 25%. Although CT is the diagnostic test of choice for evaluating children with head trauma, this procedure has disadvantages, including exposure to radiation,

**Table 360-2** Glasgow Coma Scale<sup>a</sup>

EYE-OPENING RESPONSE			
SCORE	>1 Y	≤1 Y	
4	Spontaneous	Spontaneous	
3	To verbal command	To shout	
2	To pain	To pain	
1	None	None	
MOTOR RESPONSE			
SCORE	>1 Y	≤1 Y	
6	Obeys commands	Spontaneous response	
5	Localizes pain	Localizes pain

5	Is oriented and converses	Uses appropriate words and phrases	Babbles, coos appropriately
4	Conversation is confused	Use inappropriate words	Cries but is consolable
3	Words are inappropriate	Cries or screams persistently to pain	Cries or screams persistently to pain
2	Sounds are incomprehensible	Grunts or moans to pain	Grunts or moans to pain
1	None	None	None

<sup>a</sup>The Glasgow Coma Scale score is the sum of best eye-opening, motor, and verbal responses. Scores range from 3 to 15. Derived from Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet*. 1974;2:81–84.

transport of the child away from supervision in the ED, the frequent need for pharmacologic sedation, additional health care costs, and increased time for completing the ED evaluation. Therefore, cranial CT scans should be used selectively in the ED evaluation of children with minor blunt head trauma.

A landmark prospective study conducted on children with minor head injury helped to reduce the use of unnecessary CT scans in children. Kuppermann and colleagues enrolled 42,412 patients younger than 18 years presenting within 24 hours of head trauma with GCS scores of 14 or 15. They aimed to identify children at very low risk for clinically important TBI, for whom CT might be unnecessary. They identified clinical criteria or a prediction rule for children younger than 2 years—normal mental status, no scalp hematoma except frontal, no loss of consciousness or a loss of consciousness for less than 5 seconds, nonsevere injury mechanism, no palpable skull fracture, and acting normally according to the parents. The criteria for children aged 2 years and older were normal mental status, no loss of consciousness, no vomiting, nonsevere injury mechanism, no signs of basilar skull fracture, and no severe headache. Using these criteria, which can easily be done in the clinical setting, most patients not requiring a CT scan could be identified.

In children who have a known severe head injury or are found unconscious after a sports-related

injury, coexisting cervical spine damage should be assumed until proved otherwise. Clinically significant cervical spine injury is rare in children, occurring in about 1% to 2% after blunt trauma. However, if there is a high index of suspicion, the neck should not be moved until imaging studies are completed. Appropriate immobilization requires placing the head and neck in normal anatomic alignment, which will vary depending on the age of the child. Younger children have proportionally larger heads, resulting in cervical flexion in the supine position and requiring elevation of the body to achieve correct positioning. Adult data recommend CT of the cervical spine as the imaging modality of choice, yet because of the concern for ionizing radiation in children, plain radiographs are still the initial imaging modality of choice. CT is reserved for more diagnostic certainty or if the physician is sufficiently concerned. Plain films should include cross-table lateral, anteroposterior, and odontoid views.

### Secondary Brain Damage

After TBI has been detected and the patient resuscitated, the subsequent management is directed at preventing secondary insults. The most important causes of secondary brain damage are hypoxia, systemic hypotension, and raised ICP (intracranial hypertension). To the degree possible, these situations must be

prevented. Vital signs should be frequently assessed to ensure adequacy of circulation. Shock leads to further brain injury despite adequate airway management and oxygenation. Vigorous fluid therapy to restore adequate circulating blood volume and sufficient cerebral perfusion is essential. Isotonic solutions or blood products should be administered because hypotonic solutions may promote movement of free water into damaged brain tissue, increasing the potential for cerebral edema. Some authorities have even argued for the use of hypertonic solutions in acute severe brain trauma, but this approach is not widely used. If the child is in shock, then a source of bleeding should be sought. Patients rarely sequester sufficient blood volume in the head to produce shock (notable exceptions include the infant with an expansible skull and the presence of a large subgaleal hematoma). Additional measures directed at reducing secondary brain injury include elevating the patient's head 30 degrees and keeping it in a midline position to maximize venous outflow from the cranial vault.

Intracranial pressure should be monitored and lowered if necessary. Placement of an intracranial ventricular catheter is the most accurate and reliable method for monitoring ICP. Intracranial hypertension is defined as a sustained ICP of more than 20 mm Hg. The Cushing triad is an ominous sign that implies increased ICP. This response and unilateral pupillary dilation (a sign of impending catastrophic temporal lobe herniation) should prompt administration of hyperosmolar therapy (preferably hypertonic saline, also mannitol) as a temporizing measure before obtaining an emergent CT scan. Reduction of cerebral metabolism by initiating barbiturate coma may improve outcomes and should be considered when pediatric neurosurgeons and pediatric intensive care units are available. The role of therapeutic hypothermia in the treatment of children with severe TBI is still unclear. Corticosteroids do not improve outcome when used in the acute phase management of TBI.

Antipyretics should be administered if the child has a fever. Hyperthermia may increase cerebral metabolic demands, further taxing delivery of nutrients to the injured brain. Similarly, seizures greatly increase the metabolic demands of the brain and should be treated promptly with intravenous diazepam or lorazepam, followed by intravenous phenytoin or levetiracetam. The latter should not be provided if the child is pharmacologically paralyzed because it results in an inability to detect seizure activity. Intravenous phenytoin is also advisable before transfer to another medical center. It may be difficult to see clinical seizures in children who are in the intensive care unit because of multiple factors, including altered mental status and the use of sedatives and paralytics. For this particular group of children, it may be beneficial to use continuous video-electroencephalography to avoid missing both clinical and subclinical seizure activity.

## TREATMENT

The acute care of patients presenting with TBI depends on the level of severity. The low-risk category

includes children younger than 2 years who have a GCS of 15, no signs of altered consciousness, no scalp hematoma except for frontal, and no significant mechanism of injury. These patients do not require imaging and typically only need monitoring in the ED and discharge home with a reliable caretaker. The same holds true for children older than 2 years who have a GCS of 15, no altered mental status, no signs of basilar skull fracture, no history of vomiting or headache, and no significant mechanism of injury.

Intermediate-risk children who are younger than 2 years have nonfrontal scalp hematoma, loss of consciousness for more than 5 seconds, caretakers concerned about current behavior, or high-force mechanism of injury. For patients in this risk category older than 2 years, the characteristics include history of loss of consciousness, history of emesis, severe headache, or significant mechanism of injury. Cases in this category can be managed in 1 of 2 ways: with a 4- to 5-hour period of observation and re-evaluation or with a head CT scan.

High-risk patients of any age have any of the following characteristics: GCS score of 14 or less, depressed mental status, focal neurologic findings, signs of depressed or basilar skull fracture, seizure, irritability, acute skull fracture, and bulging fontanel. All high-risk patients require a cranial CT scan.

Further management for high-risk cases may include endotracheal intubation with avoidance of hypoxemia, hypercarbia, hypotension, and hyperthermia. It is crucial to closely monitor the neurologic examination, heart rate, and blood pressure to observe for signs of impending herniation. When there is a concern for herniation, osmotic agents are typically used to reduce brain tissue edema; the agents of choice include mannitol and hypertonic saline.

## DISCHARGE HOME

Children with mild head injury who promptly recover their neurologic function, who are not suspected of being abused, and who have reliable caregivers can be discharged home with appropriate instructions. Children with normal neurologic examination findings and negative CT scans rarely have neurologic deterioration after discharge from the ED. Parents are often instructed to observe the child carefully for at least 24 hours, but they are not required to periodically awaken the child from sleep. Caregivers should return immediately to the ED if the child cannot be awakened, demonstrates decreasing mental status while awake, or develops seizures, focal weakness, increasing headache, progressive instability, or vomiting to the point of dehydration. Linear skull fractures do not require admission to the hospital if the child is asymptomatic, but they do require close observation because the force required to fracture a child's skull is significant. A reliable observer at home is required. Physicians are required to report any suspected cases of child abuse, and those children who have suffered abusive head trauma may require hospital admission for protective placement.

After hospital or ED discharge, the family should contact their pediatrician the following day and schedule an office follow-up at 1 to 2 weeks. The child's

recovery can be reviewed and further anticipatory guidance provided to the family regarding relevant neurologic sequelae of the child's head injury. Children should have between 1 and 3 days of complete cognitive rest, which includes abstaining from school, homework, cell phones, computers, video games, and television. Before returning to school, the child should be completely asymptomatic and able to perform basic academic skills without worsening symptoms. Time at school and workload should be gradually increased as tolerated with the coordination of the school teachers, counselors, and physicians. For athletes, a return-to-play protocol has been recommended by a consensus statement from the Fourth International Conference on Concussion in Sport. It is a 6-step approach with the child spending at least 24 hours in each step. It progresses from no activity to light exercise, then sport-specific exercise, then non-contact training, then full-contact practice, and finally return to play. Children younger than 2 years who have diastatic fractures (fractures that involve normal suture lines) should be evaluated again in 6 to 8 weeks to check for a *growing fracture*. These enlarging fractures occur as a result of leptomeningeal cyst formation, and they frequently require neurosurgical closure.

## PROGNOSIS

Children who experienced mild head trauma (GCS score of 13–15) are indistinguishable from their peers 1 year after their injuries. Despite this fact, significant neurologic dysfunction may be seen in the period immediately after the child's injury and may persist for weeks to months. Most children with mild TBI will have complete recovery from symptoms within 7 to 10 days; however, about 10% may have ongoing symptoms beyond 2 weeks. Those with persistent symptoms may be encompassed under the clinical criteria of postconcussion syndrome. The definition according to the World Health Organization *International Classification of Diseases*, 10th edition includes 3 or more of the following: fatigue, sleep disturbance, headache, dizziness, irritability, affective disturbance, apathy, or personality change. Most postconcussive symptoms resolve on their own after 1 month with adherence to the treatment recommendations stated in the 2012 Consensus Statement on Concussion in Sport with regard to return to school and play. However, in children who continue to have deficits, studies have found neurocognitive rehabilitation to improve neuropsychological testing scores and cognitive function. For those with vestibular disturbances such as dizziness and impaired gait, vestibular rehabilitation has been shown to be efficacious.

Children who have moderate head injury (GCS score of 9–12) and severe head injury (GCS score of 3–8) may suffer from multiple physical, cognitive, and psychological disabilities. However, prognosis is generally more favorable for head-injured children than adults. For example, children with an initial GCS score of 6 or higher have an 80% chance of achieving functional independence. Intellectual recovery continues for as long as 2 years after head injury in children; thus, long-term rehabilitative services are needed. Formal psychological assessment for staging school

re-entry and for ongoing adjustment of the child's academic curriculum should be performed.

Five percent of patients will experience seizures within the first week after their head injury. The occurrence of these early-onset seizures does not accurately predict the development of later posttraumatic epilepsy. The risk for subsequently developing epilepsy is significantly increased if seizures are present beyond the first week after head injury, particularly when severe head trauma, intraparenchymal hematoma, or depressed skull fracture occurs. With these risk factors, approximately one-third of patients will develop posttraumatic epilepsy. Electroencephalographic studies do not accurately predict its subsequent development. The use of prophylactic anticonvulsant medications does not appear to reduce the risk for its occurrence. These medications are generally not used in mild brain injury. They are indicated for children who have had severe brain injury to prevent increased ICP caused by the seizures.

## PATIENT EDUCATION

Education on preventing head injury events is an essential role for the physician. Anticipatory guidance on appropriate supervision of children, high-risk activities, and use of protective equipment such as car seats for infants and helmets for older children while biking, skateboarding, skiing, snowboarding, and snowmobiling can dramatically reduce the morbidity and mortality that result from head injury.

### WHEN TO REFER

- Deteriorating mental status
- Coma or persistent alteration in mental status
- Glasgow Coma Scale score of less than 12
- Subdural, epidural, or intraparenchymal hematoma
- Focal abnormalities on neurologic examination
- Seizures after the first week or recurrent seizures
- Shock
- Signs of Cushing triad (bradycardia, hypertension, irregular respirations)
- Suspicion of child abuse (refer to appropriate local governmental agency)
- Cervical spine injury
- Basilar skull fracture
- Depressed skull fracture
- Increasingly severe headaches
- Facial laceration or suspicion of significant trauma at other locations
- If symptoms persist beyond 2 weeks or a student athlete has multiple sports-related concussions

### WHEN TO ADMIT

- Persistent alteration in mental state
- Focal neurologic deficits
- Seizures
- Persistent vomiting that precludes adequate hydration
- Severe headache
- Suspicion of abuse

- Unreliable caregivers or observers at home
- Any injury requiring neurosurgical intervention
- CT scan indicating intracranial bleeding or brain injury

## Chapter 361

# HEART FAILURE

Paolo G. Rusconi, MD; William Harmon, MD;  
James D. Wilkinson, MD, MPH; Steven E. Lipshultz, MD

Heart failure (HF) is a common outcome of many conditions affecting the heart in children. It results from a broad spectrum of diseases that include primary and secondary cardiomyopathies, myocarditis, valvular and congenital heart defects, and coronary artery disease. Heart failure can also occur as a secondary result of chronic diseases of noncardiac origin, such as renal failure and diabetes.

For many decades, HF has been perceived as a progressive and consistently fatal condition. In the recent past, pharmacologic treatment only consisted of anti-congestive therapy with digoxin and diuretics. Now, HF is seen no longer as a “pump failure” but rather as a more complex condition resulting from changes at the molecular, cellular, interstitial, structural, and functional levels that negatively reshape and remodel the heart. This improved understanding has led to a broader range of medical and surgical therapies for HF in patients of all ages.

Heart failure can occur in infants or children of any age, but up to 90% of cases arise during infancy from a variety of congenital conditions. This chapter reviews the pathophysiologic mechanisms of HF, especially as they relate to differences in age at presentation. The signs and symptoms of HF are discussed, as are specific causes and associated findings. In many children, HF results in a chronic, smoldering, and initially compensated course that may not be recognized early. Finally, the chapter presents various medical and surgical treatments for specific conditions. Understanding the causes and associations of pediatric HF and being able to recognize its signs and symptoms will help with early diagnosis, which may in turn improve the clinical outcomes for these challenging patients.

## PATHOPHYSIOLOGIC FEATURES

Left ventricular force differs at each developmental stage. In general, the contractile efficiency is greater in neonates than in fetuses and is similarly better in adults than in neonates. Thus for a particular left ventricular preload, cardiac output or stroke volume rises progressively from the fetal to the neonatal and through to the adult stages of life. Although the mechanisms of this relationship are not clear, the properties

of contractile proteins, ion channels, and cell surface receptors are expressed differently at each developmental stage. For example, the sodium-potassium pump is an ion channel largely responsible for maintaining the resting sodium gradient along the sarcolemmal membrane. Although of uncertain functional consequence, this channel has been shown to be less active in the immature myocardium. Additionally, developmental changes have been documented in terms of catecholamine receptor expression and second messenger system function. Thyroid hormone, cortisol, and catecholamine release surrounding birth lead to a transient increase of myocardial contractility. Catecholamine responsiveness is thereafter reduced, increasing again as sympathetic innervation subsequently matures. Animal studies suggest that neonates operate closer to their maximal inotropic potential than do adults, and neonatal hearts seem to have less diastolic compliance (they are “stiffer”) and therefore are more sensitive to preload variation than a normal adult heart (Table 361-1).

Heart failure is most often characterized by a decrease in cardiac output. Low cardiac output leads to the activation of several major neurohormonal compensatory systems. The renin-angiotensin-aldosterone system (RAAS) is activated as a result of decreased renal perfusion. This decrease in perfusion has several physiologic effects, including systemic vasoconstriction that increases systemic vascular resistance, which raises the blood pressure toward normal. Aldosterone release leads to salt and water retention, thereby expanding the circulating blood volume. Heart failure also leads to central activation of the vasopressin system, which promotes a further increase in circulating blood volume through renal water retention. This excess intravascular volume contributes directly to the symptoms of congestive HF.

Importantly, low cardiac output produces marked sympathetic activation that increases serum levels of circulating catecholamines. This acute baroreceptor mechanism restores blood pressure by producing systemic vasoconstriction and increasing myocardial contractility. These responses may have short-term advantages, but long-term catecholamine exposure is clearly harmful to the failing heart. Chronic sympathetic activation adversely affects the heart through a broad series of both intuitive and surprisingly interdependent mechanisms. For example, myocyte apoptosis (programmed cell death) occurs with prolonged catecholamine elevation. Peripheral vasoconstriction further raises systemic vascular resistance, increasing myocardial workload and enabling ventricular remodeling and hypertrophy. Sympathetic input augments the RAAS response, again increasing systemic vascular resistance and volume expansion. Progressive cardiac remodeling with fibrosis often develops, which is thought to increase myocyte automaticity and the risk for arrhythmia. As contractility and stroke volume fall, faster heart rates are required to maintain cardiac output. This resulting tachycardia increases myocardial oxygen demand in a failing organ that may be reaching the limits of its oxygen delivery capacity. Thus, nearly all compensatory mechanisms are designed to maintain stroke volume and cardiac output but lead to increased cardiac demand that hasten progressive HF.

Little is known about differences in the RAAS response to cardiac insult at different stages of development. There is evidence that in normal subjects, RAAS activity is increased in infancy and childhood compared with adults. Plasma renin activity and renin concentration are more elevated in infancy than adulthood and tend to decrease with age; plasma aldosterone also is elevated in infancy, and its level decreases

**Table 361-1** Major Differences Between Neonatal and Mature Hearts

CHARACTERISTIC	NEONATAL	MATURE
<b>PHYSIOLOGIC</b>		
Contractility	Limited	Normal
Heart rate dependence	High	Low
Contractile reserve	Low	High
Afterload tolerance	Low	Higher
Preload tolerance	Limited	Better
Ventricular interdependence	Significant	Less
<b>CALCIUM ION CYCLING</b>		
Predominant site of calcium ion flux	Sarcolemma	Sarcoplasmic reticulum
Dependence on normal ionized $\text{Ca}^{2+}$	High	Lower
Circulating catecholamines	High	Lower
Adrenergic receptors	Downregulation, insensitive $\beta_2$ , $\alpha_1$ predominant	Normal, $\beta_1$
Predominant innervation	Parasympathetic predominates; sympathetic incomplete	Complete
Cytoskeleton	Higher water content	Lower water content
Cellular elements	Incomplete sarcoplasmic reticulum, disorganized myofibrils	Mature sarcoplasmic reticulum, organized myofibrils

over the first 4 years of life. Angiotensin-converting enzyme (ACE) inhibitor can reverse cardiac remodeling in children, similar to in adults. In a prospective study of 24 children aged 0.3 to 16 years with volume overload secondary to aortic mitral regurgitation, Mori showed that long-term use of ACE inhibitors is effective in reducing left ventricular volume and hypertrophy compared with controls.

## **SIGNS AND SYMPTOMS OF CONGESTIVE HEART FAILURE**

Heart failure in children occurs most frequently in the very young. A thorough clinical history often provides clues to the presence and causes of HF.

### **Feeding**

Feeding is exercise activity for an infant. Heart failure impairs tissue oxygen delivery and alters lung function through pulmonary edema and airway obstruction. When HF progresses and lung function deteriorates, infants typically become tachypneic as their work of breathing increases. Tachypnea increases caloric expenditures while limiting the ability to feed effectively. For these reasons, a detailed history of feeding and growth is essential when screening an infant for heart disease. The average 6-week-old child consumes roughly 3 to 4 ounces of formula per feeding and nutritively sucks no longer than 20 minutes per feeding. A lower intake or a much longer feeding time may be of concern. Similarly, infants tend to gain 10 to 30 g/day and consume more than 90 kcal/kg/day.

Children with HF often have greater nutritional needs because of increased metabolic demands and may require 150 kcal/kg/day to gain adequate weight. Infants with HF often feed only in short, interrupted periods, and feedings may be associated with tachypnea and diaphoresis. Parents and caregivers will report that the infant feeds all day long, yet the total intake remains low, and the associated weight gain is poor. In older children, chronic HF results in malnutrition. Weight is usually the initial anthropometric measurement to be affected, followed by delays in the normal development of height and eventually head circumference. Evaluating growth velocity is critical to understanding the true nutritional effect of HF.

### **Activity Level**

Children with new-onset HF usually become either less active or more irritable and anxious.

### **Tachycardia**

Resting heart rates are low in normal infants and children but may be persistently and abnormally high in children with HF.

### **Tachypnea**

Sleeping respiration rates are typically low in healthy infants and children but may be higher in children with HF.

### **Rales**

Rales are less likely to be found in infants and young children with HF than in older children. In a young child,

rales may suggest active pulmonary disease. In advanced HF, bronchial edema can result in airway obstruction and “cardiac wheezing,” which is most common in younger infants. Chest radiographs in infants with HF show classic signs of overinflation and air trapping.

### **Jugular Venous Distention**

Although jugular venous distention may be seen in many older children with HF, it is less frequent in infants and young children, probably because observing their jugular veins is difficult and right-sided filling pressures may be lower than those often seen in adults.

### **Hepatomegaly**

The liver is frequently enlarged in infants and children with HF. Measuring the total liver span by percussion is more useful diagnostically than determining how far the liver edge extends below the right costal margin. The left lobe of the liver is often enlarged in infants and young children who have HF, and thus a palpable liver edge that crosses the midline suggests HF.

### **Gallops**

A third heart sound ( $S_3$ , an early diastolic, low-pitched sound corresponding to the rhythm of “Kentucky,” where the “ky” is the third sound) is common and normal in healthy children. An  $S_3$  can be heard in patients with HF and therefore may also be a pathologic gallop. In contrast, an  $S_4$  gallop (the sound corresponding to the rhythm of the first syllable of “Tennessee”) is always pathologic but is less common in pediatric HF. The  $S_4$  gallop is thought to be generated by the decreased compliance of a dilated, failing ventricle.

### **Pulses and Perfusion**

As discussed previously, HF is often associated with decreased cardiac output and peripheral vasoconstriction (a high “SVR” state). This peripheral vasoconstriction occurs through a variety of mechanisms (eg, increased catecholamine levels, renin-angiotensin system response), resulting in cool and pale extremities with decreased (“thready”) distal pulses. In some cases, the infant may be overtly mottled or cyanotic. The character of the pulses in the arms and legs should also always be compared because reduced or delayed pulses in the leg may indicate coarctation of the aorta, an interrupted aortic arch, or a similar condition requiring prompt treatment.

### **Arrhythmias and Sudden Death**

Arrhythmias may be both a cause and effect of HF in children and young adults. Ventricular dysfunction resulting from dilated cardiomyopathy may be associated with high-grade ectopy, which may increase the risk for death in association with HF. Similarly, unexplained syncope or palpitations in children may be the signs of an undiagnosed cardiomyopathy. Syncope, in particular, may predict sudden death in some children and may prompt interventions such as the placement of an automatic implanted cardiac defibrillator.

### **Heart Failure Scoring Systems**

Accurate patient-specific or population-based discussions of HF require standard terms and classifications.

Furthermore, because heart disease and HF are common in adults, discussions of adult HF are used, to some extent, toward the care of children. However, congenital heart disease and HF, comparative to large adult populations, remain relatively rare conditions in children. In adults, the New York Heart Association classification is widely used to indicate functional limitations resulting from HF. Unfortunately, this classification system is not particularly useful in infants and children because developmental stages greatly affect physical activities and exercise capabilities across age groups.

The Ross classification (Table 361-2) and the Ross scoring system (Table 361-3) are similar to the New York Heart Association classification and are validated for grading pediatric HF (Table 361-4). Both the New York and the Ross systems describe only functional status, without regard to the cause or the course of disease progression. Adult treatment guidelines published by the American College of Cardiology (ACC) and the American Heart Association (AHA) use the New York Heart Association classification but add another stage of disease to better indicate severity and to guide intervention. In 2004, the International Society for Heart and Lung Transplantation used these classifications, interpreted by expert pediatricians, as models when creating their practice guidelines for managing HF in children. These practice guidelines do differ substantially from those for adults, often as a result of the lack of pediatric-specific evidence. The guidelines also propose an HF staging system for infants and children that is also modeled after the adult systems and that uses the age-specific findings from the Ross classification (Table 361-5).

## LEADING CAUSES OF CONGESTIVE HEART FAILURE AT DIFFERENT AGES

The age at onset of HF in children, especially in infants, is an important initial clue about the cause of disease. Structural congenital disease tends to present

early in life, whereas progressive diseases, such as dilated cardiomyopathy, usually present in older children. The transition from fetal to postnatal circulation requires precise steps, any of which may be compromised and lead to HF. Some examples of age-related presentations are described below.

### Prenatal Period

Fetal cardiomyopathy and HF can result in hydrops fetalis and fetal demise. Fetal heart disease is now commonly identified in developed nations where routine prenatal ultrasound examinations are regularly performed. The causes of fetal HF are diverse and can arise from maternal (placental, rheumatologic), fetal (anatomic, arrhythmic), and infectious (viral) sources. Viruses affecting the fetus are generally the same as those found postnatally (eg, parvovirus, enteroviruses, adenovirus). Prolonged supraventricular tachycardia

**Table 361-2** Ross Classification of Heart Failure in Infants and Young Children

CLASS	DESCRIPTION
I	No physical limitations or symptoms, essentially normal and healthy seeming
II	Mild tachypnea or diaphoresis with feeding in infants Dyspnea on exertion in older children No growth failure
III	Marked tachypnea or diaphoresis with feeding or exertion Prolonged feeding times Growth failure from congestive HF
IV	Symptoms at rest with tachypnea, chest retractions, grunting, or diaphoresis

HF, heart failure.

**Table 361-3** Ross Scoring System of Heart Failure in Infants

CHARACTERISTIC	0 POINTS	1 POINT	2 POINTS
Volume per feed, oz	>3.5	2.5 to 3.5	<2.5
Time per feed, min	<40	>40	...
Respiratory rate, breaths/min	<50	50–60	>60
Heart rate, beats/min	<160/min	160–170/min	>170/min
Respiratory pattern	Normal	Abnormal	...
Peripheral perfusion	Normal	Decreased	...
S <sub>3</sub> or diastolic rumble	Absent	Present	...
Liver edge from costal margin, cm	<2	2 to 3	>3
Interpretation: The severity of congestive heart failure			
Totals			
No CHF	0–2 points	—	—
Mild CHF	3–6 points	—	—
Moderate CHF	7–9 points	—	—
Severe CHF	10–12 points	—	—

CHF, Congestive heart failure; S<sub>3</sub>, third heart sound.

is often not well tolerated by fetuses and may require maternally administered antiarrhythmic therapy. Such fetuses should be closely monitored and managed with a multidisciplinary team consisting of a perinatologist, cardiologist, and neonatologist. Maternal drug toxicity, efficacy, and the effect of premature delivery need to be considered in treatment decisions. Pediatric cardiologists with expertise in fetal development are invaluable for directing the fetal and postnatal care of these infants.

**Delivery Room or the Immediate Presentation of Compromised Cardiovascular Status**

**Persistent Pulmonary Hypertension**

Severe pulmonary hypertension may develop in infants aspirating meconium or experiencing acidosis from a complicated delivery. High pulmonary pressures result in right-to-left blood flow across a patent ductus arteriosus and a condition known as *persistent pulmonary hypertension* or *persistent fetal circulation*. If severe, this condition can lead to right ventricular failure and low cardiac output in conjunction with possibly severe overlying hypoxic lung disease.

Many therapies for neonates with persistent pulmonary hypertension are directed to improving right ventricular cardiac output and reducing the severity of hemodynamic compromise. Fluid administration, inotropic use, ventilator adjustments to reduce pulmonary

vascular resistance, and extracorporeal circulatory support (extracorporeal membrane oxygenation, or ECMO) are standard hemodynamic interventions often required to treat this challenging disease. Septic shock should always be considered in the differential diagnosis of a sick neonate and typically requires evaluating and treating with antibiotics any infant presenting with this level of life-threatening disease.

**Hematologic Abnormalities and Neonatal Heart Failure**

Acute or chronic anemia can compromise the hemodynamic status in newborns. Conversely, polycythemia, as seen in infants of diabetic mothers, can lead to hyperviscosity, sludging, and HF. Treatment of these conditions is determined by the severity of the infant's clinical condition and the specific context of care. Severe anemia can result in hydrops fetalis with high-output HF or acute cardiogenic shock, depending on the time course and duration of blood loss. Acute blood loss, from abruptio placenta, for example, can be managed with aggressive volume resuscitation and red cell transfusion. On the other hand, a chronic anemia, such as that caused by Rh sensitization, may be associated with some degree of volume expansion and physiologic compensation. In this case, the infant will have a chronic volume overload. In this setting, red cell replacement needs to be monitored carefully to avoid acute volume overload and progressive HF-associated pulmonary edema. Patients with severe anemia may benefit from double-volume exchange transfusions, particularly if antibodies may need to be removed. In other cases, a more gradual transfusion, coupled with diuretic administration and careful monitoring, may be appropriate.

**Electrolyte and Metabolic Causes of Cardiac Compromise**

Electrolyte abnormalities can lead to early hemodynamic compromise. Neonates are exquisitely sensitive to hypoglycemia and hypocalcemia. The neonatal myocardium uses glucose for energy metabolism, and

Table 361-4 New York Heart Association Functional Classification of Heart Failure	
CLASS	DESCRIPTION
I	No limitations to normal exertion
II	Symptoms on ordinary exertion
III	Symptoms with less than ordinary exertion
IV	Symptoms at rest

Table 361-5 The International Society for Heart and Lung Transplantation Proposed Heart Failure Staging for Infants and Children	
STAGE	INTERPRETATION
A	Patients with increased risk for HF but who have normal cardiac function and no evidence of cardiac chamber volume overload. Some sources of increased risk: previous exposure to cardiotoxic agents; family history of heritable cardiomyopathy; univentricular heart; and congenitally corrected transposition of the great arteries.
B	Patients with abnormal cardiac morphology or function, with no past or present symptoms of HF. Examples: aortic insufficiency with left ventricular enlargement; history of anthracycline exposure with decreased left ventricular systolic function.
C	Patients with underlying structural or functional heart diseases and past or present symptoms of HF.
D	Patients with end-stage HF requiring continuous infusion of inotropic agents, mechanical circulatory support, cardiac transplantation, or hospice care.

HF, Heart failure.  
Adapted from Rosenthal D, Chrisant MR, Edens E, et al. International Society for Heart and Lung Transplantation: practice guidelines for the management of heart failure in children. *J Heart Lung Transplant*. 2004;23:1313–1333. Copyright © 2004, Elsevier, with permission.

episodes of hypoglycemia can lead to hemodynamic collapse. Neonates generally have limited fat and energy stores, compared with older children. A newborn with low blood sugar and signs of poor perfusion will often improve when blood sugar levels return to normal. Similarly, hypocalcemia is another metabolic cause of hypotension and hemodynamic collapse on the first day of life. Current thinking is that neonates generally do not have fully developed and efficiently regulated intramyocardial calcium stores (the sarcoplasmic reticulum complex) and therefore depend greatly on serum ionized calcium to maintain normal myocardial contractility. Restoring normal calcium levels can reduce signs or symptoms of hypotension and low cardiac output. Hypoglycemia and hypocalcemia often occur together in infants of diabetic mothers.

### Arrhythmias

Heart rate abnormalities may also lead to HF in the fetus, newborn, or older child. In general, supraventricular arrhythmias are well tolerated, at least in the short term. Most older children will sense palpitations and will immediately seek attention at the onset of sustained tachycardia. In neonates and infants unable to verbalize such concerns, tachycardia may persist to the point of ventricular compromise. Supraventricular arrhythmias in neonates, which are often re-entrant rhythms through an accessory bypass tract, occur at rates of 250 to 300 beats per minute. At such high pulse rates, cardiac output is low as a result of incomplete diastolic relaxation, abnormal coronary perfusion, and eventual ventricular dysfunction. As such, tachycardia-associated cardiomyopathy may begin after a period of unrecognized, sustained tachycardia. In this case, sinus rhythm should be restored immediately through vagal maneuvers, medications (adenosine intravenously), or electrical cardioversion. Infants are then generally treated with either oral beta blockers or digoxin for long-term rhythm control.

Bradycardia can also cause acute or chronic HF in any age group. In general, symptomatic HF is seen in association with heart rates less than 60 beats per minute in infants and less than 40 beats per minute in older children and adults. Fetal and neonatal complete heart block is classically associated with maternal lupus erythematosus that often requires pacemaker placement. Direct myocardial injury beyond the conduction system has also been associated with neonatal lupus syndrome, perhaps as a direct cause of a progressive dilated cardiomyopathy.

### Heart Failure in the Neonate

Congenital heart disease in infants is often diagnosed in the first few days after birth. Several classic presentations should be kept in mind. For example, severe respiratory distress with progressive pulmonary edema and a small heart (indicated by the radiographic image of a “snowman in a snowstorm”) develops early in infants with obstructed total anomalous pulmonary venous connections. This relatively rare lesion must be identified early because surgery is the only effective intervention. Echocardiography can confirm the diagnosis.

A wide variety of congenital heart diseases present in the first several days of life. Symptoms occurring during this period warrant a high suspicion of a closing ductus arteriosus that may have been physiologically beneficial. These benefits depend on the anatomy involved. In right-sided obstructive lesions, such as pulmonary atresia, severe tetralogy of Fallot, or tricuspid atresia, the ductus initially is a source of pulmonary blood flow. With ductal closure, infants become progressively cyanotic and progressively symptomatic. In transposition of the great arteries, ductal flow increases pulmonary blood flow, increasing left atrial pulmonary venous return and beneficial atrial intracirculatory mixing. Again, in some infants, ductal closure will precipitate acute cyanosis, which may be severe and lead to acute hypoxic symptoms. In left-sided obstructive lesions, such as hypoplastic left heart syndrome, critical aortic stenosis, or critical coarctation of the aorta, infants depend on ductal blood flow to provide a source of systemic blood flow. Infants with these lesions become critically ill when the ductus closes from inadequate systemic perfusion. Prostaglandin E<sub>1</sub> infusion maintains ductal patency and is life-saving in these situations. Prostaglandin infusion is now routine and allows unhurried surgical planning for most cyanotic duct-dependent congenital heart defects.

The ductus closes in most children after 3 or 4 days of life. However, in some lesions, such as coarctation of the aorta, ductal patency can be prolonged. In fact, severe or critical coarctation of the aorta commonly presents 1 to 2 weeks after birth and is often accompanied by ventricular dysfunction or signs of poor renal and intestinal perfusion (eg, absent femoral pulses, acidosis, elevated blood urea nitrogen-to-creatinine ratio). Prostaglandin treatment at this age is usually effective, at least for partially reopening the ductus and restoring flow to the lower circulation. Surgery is then indicated when the infant has recovered from any acute organ dysfunction, typically within a few days after an acute presentation.

### Heart Failure in the First 3 Months of Life

Left-to-right shunts commonly lead to pulmonary overcirculation as pulmonary vascular resistance falls toward normal adult values at 4 to 8 weeks of age. Infants with large ventricular septal defects are the quintessential example of this overcirculation. As pulmonary vascular resistance falls, so does right ventricular pressure. This reduction in pressure allows a progressively larger volume of left ventricular blood to cross the ventricular-septal defect and enter the pulmonary circulation, essentially stealing systemic cardiac output from the left ventricle.

Falling systemic cardiac output activates several acute and chronic compensatory mechanisms. Activated carotid and aortic arch baroreceptors increase catecholamine release. Catecholamines produce tachycardia and increase inotropy and peripheral vasoconstriction. The rise in systemic vascular resistance is favorable in that blood pressure increases toward normal but is unfavorable because the rise increases again the volume of ventricular-level shunting. Loss of renal blood flow from ventricular shunting

activates the RAAS. Through angiotensin II-mediated vasoconstriction, systemic vascular resistance increases further, thereby re-exacerbating the volume of the intracardiac shunt. Aldosterone effects lead to volume expansion by way of salt and water retention. The final result is an infant who has high catecholamine levels, tachycardia, constricted peripheral vasculature and cool extremities, and pulmonary edema caused by volume overload. These pathophysiologic conditions occur in all low-cardiac output states, and their reduction explains the mechanistic benefits of anti-HF drugs (diuretics, ACE inhibitors,  $\beta$ -adrenergic blockade, antialdosterone agents). Other examples of common left-to-right shunts include atrial-septal defects, complete atrioventricular canal defects, and patent ductus arteriosus.

From the above discussion, it should be clear that the timing of presentation often suggests the cause of the infant's HF. Most of these lesions can be surgically corrected in early infancy, returning the patient's physiologic state back to normal.

### Heart Failure in Months 6 to 12 of Life

In the second 6 months of life, metabolic, genetic, infectious, and inflammatory cardiomyopathies become more common because most children with congenital disease have already been identified. Children with metabolic or genetic cardiomyopathy tend to be perceived as asymptomatic with only mild, clinically unrecognized disease early in the course of their illness. Disease typically becomes evident during evaluation for a presumed or supervening, often viral, illness. Symptoms, such as anorexia and vomiting or respiratory distress and hypoxia, should prompt a more thorough evaluation to identify any underlying cardiac disease. Glycogen storage diseases, hypertrophic cardiomyopathies, and infectious and inflammatory diseases, such as HIV infection and Kawasaki disease, are but a few of the diverse causes of cardiac dysfunction in this age group.

### Heart Failure in Years 1 to 18 of Life

Heart failure in children older than 1 year occurs most commonly with comorbid severe or chronic illnesses. For example, a child treated for cancer is at risk for HF during and after treatment with anthracycline-containing chemotherapy or radiation to the chest. This risk for HF persists lifelong as a result of the inherent cardiotoxicity and myocyte loss induced during cancer treatment. The leading indications for pediatric heart transplantation, after failed medical management of HF, are congenital heart disease and cardiomyopathy. Dilated cardiomyopathy is the leading cause of progressive HF and cardiac transplantation during childhood and adolescence. When examined systematically, dilated cardiomyopathy is most commonly an idiopathic disease resulting from unknown insults in two-thirds of cases. Although commonly implicated, only about 16% of dilated cardiomyopathy occurs as a result of a viral myocarditis. Many viruses have been implicated in the development of acute viral myocarditis, including the enteroviruses, adenoviruses, and seasonal influenza. Although rare, acute toxic ingestions, malignant hypertension, malnutrition and

eating disorders, and hypothyroidism have all been associated with acute and subacute cardiac failure. Careful patient histories can help guide appropriate etiologic studies.

## THERAPY FOR CONGESTIVE HEART FAILURE IN CHILDREN

### Pharmacotherapy

Pharmacologic therapy for chronic pediatric HF is based mainly on precedent and extrapolation from the vast data on adults. Given the relatively low incidence of HF in children, pediatric-specific, evidence-based data to inform treatment are limited. Historically, treatment has consisted mainly of anticongestive therapy with diuretics and digoxin. The AHA and the American College of Cardiology (ACC) nearly universally recommend ACE inhibitors and  $\beta$ -adrenergic antagonists as the mainstays of treatment for adults. Aldosterone antagonists have also been recently added as standard interventions for most stage C HF patients. Standard adult practice guidelines recommend titrating diuretics to achieve euvolemia. Digoxin is recommended to treat symptoms, but its use has not improved survival.

Unfortunately, the rationale for using these drugs to treat pediatric HF is limited by the paucity of trials in children. No large, randomized trials of ACE inhibitors for treating pediatric HF have been conducted, and the results of other studies remain controversial, mainly because of small sample sizes. One study showed the beneficial effect of enalapril on systolic function and left ventricular size and mass in children with doxorubicin-induced cardiomyopathy over 6 years of treatment. However, all left ventricular characteristics deteriorated to baseline cardiac function from 6 to 10 years on treatment. Conversely, a 10-week, randomized, double-blind, placebo-controlled crossover trial in 18 patients after a Fontan procedure showed that enalapril did not improve cardiac index or exercise duration.

Data on beta blockers for treating pediatric HF are similarly limited. Several early studies showed that carvedilol (a nonselective beta blocker) improved symptoms and function in children with HF. Conversely, the one randomized, multicenter study of children with ventricular dysfunction treated with carvedilol found no benefits. This study did, however, find that systolic function and functional class tended to improve in the subset of children with cardiomyopathy. Over 4 years, this study enrolled 161 patients with symptomatic HF secondary to systemic ventricular dysfunction with dilated cardiomyopathy or congenital heart disease. Patients were randomly assigned to receive low-dose carvedilol, high-dose carvedilol, or placebo for 8 months. The primary outcome was a composite of several HF outcomes. Although the results were mainly negative, adverse events were less than expected, suggesting that the trial may have been underpowered. As a result of the foregoing, consensus guidelines for managing pediatric HF incorporate experience, opinion, and data from adults and children.

Angiotensin-converting enzyme inhibitors, beta blockers, aldosterone antagonists, and even diuretics

target maladaptive compensatory responses in HF to lessen the long-term cardiac work load. The rarity of children with HF means that a pediatric cardiologist should generally direct their care.

Acute or decompensated HF is typically treated in the intensive care unit. In AHA and ACC staging, patients with severe symptomatic HF at rest have decompensated, stage D, disease. Heart failure in this stage is not expected to resolve with the routine use of oral medications and requires more aggressive interventions. Short-term symptomatic relief can often be provided by intravenous inotropic agents (eg, milrinone, dobutamine, epinephrine). These agents are for short-term use only, however, because long-term administration of any of them reduces survival. Children with acute decompensation typically receive temporary inotropic support in an attempt to return them to oral medications. Should this attempt fail, then more invasive therapy, such as mechanical circulatory support or heart transplantation, is considered for some patients. In others, comfort care with palliative inotropic infusions or hospice is appropriate.

### Arrhythmias

In addition to pharmacotherapy for treating the specific symptoms of HF in children, arrhythmias must always be managed. Arrhythmias are a major cause of morbidity and mortality in these children, especially in the later stages of disease. Short-term treatment with intravenous antiarrhythmic agents and cardioversion or defibrillation should be considered for all hemodynamically unstable children. Long-term suppressive therapy or radiofrequency ablation of appropriate conditions may be required to treat chronic arrhythmias. In adults with HF and ischemic or dilated cardiomyopathy, implantable cardiac defibrillators have greatly improved survival. Data in children with HF are limited, and no clear guidelines for placing implantable cardiac defibrillators or for cardiac resynchronization therapy are available for these children. The guidelines currently in use are part of the general recommendations for device-based therapy published in 2008. Pediatric experience in these areas is growing, and in general, the indications for placing cardiac defibrillators in children are similar to those for adults.

### Nutritional Management

The classic problem of failure to thrive remains a major challenge in caring for children with HF. Weight gain and linear growth in children with congenital heart disease are often delayed. Poor growth seems to be an overall marker for poor outcomes after either medical or surgical interventions. Treating failure to thrive is generally approached systematically, beginning with basic patient and parental counseling to optimize feeding and to increase caloric intake.

Breastfeeding is less stressful than bottle feeding for infants and should be promoted when possible. The decision to breastfeed or bottle feed should be made on an individual basis by consensus among parents, the primary care physician, and other health care professionals familiar with the needs of the infant. Gastrostomy placement and parenteral feeding should be considered for severely malnourished infants, in

part because after placement, the infant will not incur the energy costs of feeding.

Most congenital heart defects can be corrected or palliated surgically, often in the neonatal period. Early anatomic correction is aimed at alleviating the condition that led to HF in the first place, thereby preventing or alleviating chronic malnutrition. Despite great surgical advances, cardiac surgery in underweight infants still shows increased surgical risk. The risk and benefits of a specific intervention must be considered if an infant continues to fail to thrive after trying all other aggressive feeding and nutrition measures. Surgery may be necessary and advisable, even if the infant is not at an ideal weight. Other nutritional considerations common in children with HF include electrolyte abnormalities associated with diuretic use and balancing fluid intake in situations of HF-associated volume overload.

### Biomarkers

Cardiac myocytes and interstitium are affected by changes at the molecular, cellular, structural, and functional levels by a complex interaction of enzymes, hormones, and other biologic markers of cardiac stress, myocyte injury, or malfunction. Biomarkers are becoming more important for their ability to inform the diagnosis, prognosis, and management of HF. Brain natriuretic peptide (BNP) and its inactive form, N-terminal pro-brain natriuretic peptide (NT-proBNP), have been studied extensively in adults with HF. Studies in children are still in an early phase of development and are limited by small samples. In children and adolescents, BNP level has determined the presence of cardiac disease in acute care settings and may indicate the presence of left ventricular volume and pressure overload from shunting. Price et al found that in children with HF, a BNP level greater than 300 pg/mL was highly sensitive and specific for predicting morbidity and mortality. In a retrospective study of 36 children with dilated cardiomyopathy, Rusconi et al found that increases in NT-proBNP were associated with echocardiographic indices of advancing HF. An NT-proBNP level greater than 1,000 pg/mL was 95% sensitive and 80% specific in identifying children with constant or intermittently severe (functional class III or IV) symptoms.

In a study of 19 patients with HF secondary to both dilated cardiomyopathy and congenital heart disease, Ratnasamy et al found that levels of plasma NT-proBNP, hsCRP (high-sensitivity C-reactive protein), TNF- $\alpha$  (tumor necrosis factor- $\alpha$ ), and sTNF-RII (TNF- $\alpha$  receptor II) were associated with functional class and echocardiographic indices of left ventricular function. As in the above study, NT-proBNP and hsCRP levels were significantly higher in patients with more severe HF symptoms and discriminated between stages of HF. Similarly, TNF- $\alpha$  levels correlated with markers of declining left ventricular function.

The association of natriuretic peptide with functional status and echocardiographic indices of left ventricular dysfunction in children with HF and its ability to predict outcome may be useful in diagnosing and managing HF. Natriuretic peptide levels may provide an objective assessment of the severity of HF in

these challenging patients, who are undergoing developmental and hormonal changes. Brain natriuretic peptide levels may contribute to an early diagnosis, particularly in high-risk patients, allowing earlier medical interventions with the hope of preventing and reversing some of the remodeling processes that characterize HF.

The specific roles and potential uses of individual molecular biomarkers need further study. These biomarkers arise from several classes of molecules, including inflammatory molecules, neurohormones, products of myocyte injury, oxidative stress, and markers of extracellular matrix remodeling. Currently only natriuretic peptide levels (BNP and NT-proBNP), hsCRP (a biomarker of generalized inflammation) and cardiac troponin T or I (biomarkers of myocyte injury) are used routinely in children with heart failure, although as biomarker research advances new biomarkers may be added to clinical evaluations in the future. Eventually, specific biomarker panels may provide objective data to inform comprehensive risk assessment, guide medication choices, and monitor the efficacy and titration of ongoing medical and surgical interventions.

### Cardiac Transplantation

Surgical correction of congenital cardiac defects is central to the modern management of cardiac failure in infants and children. Most congenital defects are amenable to surgical repair or palliation, and most surgeries can be performed during infancy. However, residual lesions and cardiac dysfunction may occur or progress after repair. In cases of progressive cardiac dysfunction, cardiac transplantation is effective, is fairly widespread, and has a 1-year survival rate greater than 90% and a median survival time ranging from 11 years for adolescents to 18 years for infants. After transplantation, overall survival and quality of life are excellent for most patients. More than 90% of children report no activity limitation 5 and 10 years after transplantation.

Cardiac transplantation should be considered when expected survival is less than 2 years, the patient's quality of life is unacceptably poor, or there are no other surgical options. The risk for death in children waiting for cardiac transplantation is at least 17%, so early referral to a HF or transplantation center is essential. A thorough pretransplantation evaluation is required to assess the potential for long-term complications, determine the cause of cardiac disease, and identify any contraindications to transplantation, including certain metabolic or genetic disorders. The patient should be on the highest tolerable dosages of the appropriate medications, and pretransplantation nutritional status should be maintained to prevent cachexia and to optimize both presurgical and postsurgical outcomes.

### Mechanical Circulatory Support

Mechanical circulatory support is most commonly provided with ECMO. This technology extends cardiopulmonary bypass from the operating room into the intensive care unit to provide circulatory support for long periods. Its judicious use has contributed to

improved outcomes in a variety of critical diseases over the past several decades. As a result, many physicians can skillfully apply ECMO and manage patients on it. For patients with acute or chronic progressive disease or decompensated HF, ECMO can provide full cardiopulmonary function. This and other forms of mechanical circulatory support can also be used temporarily to support patients through periods of reversible illness, such as acute myocarditis, uncontrolled arrhythmia, or even an episode of myocardial rejection after cardiac transplantation. Mechanical support is also indicated as a bridge to cardiac transplantation. The advantages of ECMO are that it is familiar, can be deployed relatively quickly, and can provide pulmonary support to patients with concurrent respiratory disease. Its disadvantages are its relatively short duration of use and the associated complications, including hemorrhage, infection, and potential neurologic impairment.

Several types of ventricular assist devices (VADs) can provide mechanical cardiac support in the absence of primary lung disease. This technology consists of a variety of pneumatic pumps or rotary impeller devices that can provide an increased duration of circulatory support, mainly in adult populations. Experience, technologic advancements, and miniaturization have expanded VAD use, such that it is now a standard of care in cardiac transplantation centers when treating ventricular failure in children. Ventricular support is generally preferred to ECMO as a bridge to cardiac transplantation because it is safer and has better neurologic and transplant outcomes. Whereas ECMO can generally be used for days to weeks, VADs are more typically used from weeks to months. Regardless of the system, mechanical circulatory support requires great expertise, institutional commitment, and expense. Mechanical support has become a standard and essential component of care in intensive care units before transplantation, and its use will likely increase as the technology is refined.

### SUMMARY

Heart failure can occur at any age in infants and children. Epidemiologic data confirm that HF is most common during the first year of life. Although it can be acute and fulminant, HF is most often a chronic, smoldering process that causes substantial morbidity and mortality. Early recognition of the signs and symptoms of HF may allow treatment that can reduce morbidity and improve the child's quality of life (Box 361-1). Medical and surgical therapies are often life-saving, after the underlying condition is identified. The causes of HF vary with the age of the child at the time of diagnosis. Congenital defects dominate in younger patients, whereas chronic disease and underlying illnesses are more common in older patients. Primary care physicians should strive to make an early diagnosis, to address growth and nutritional concerns, and to institute cause-specific treatment under the direction of a pediatric cardiologist. Medical and technologic advances promise new surgical and therapeutic options for treating heart disease in all ages. Coming developments in preventing and managing pediatric heart disease will likely take the

### BOX 361-1 Highlights From International Society for Heart and Lung Transplantation Recommendations for Managing Pediatric Heart Failure<sup>a</sup>

1. The underlying cause of new-onset ventricular dysfunction (HF stages B, C, and D) should be diligently sought in all patients. In selected patients, the search may include metabolic and genetic considerations. Invasive techniques, including myocardial biopsy, may also be considered in selected cases. In infants, coronary artery anomalies and other anatomic causes of HF need to be ruled out.
2. First-degree relatives of patients with new-onset ventricular dysfunction caused by dilated cardiomyopathy (HF stages B, C, and D), should be screened for the presence of similar disease.
3. Fluid retention associated with ventricular dysfunction (HF stage C) should be treated with diuretics to achieve euvolemia, using clinical criteria of fluid status and cardiac output (daily weight, respiratory status, monitoring hepatomegaly, monitoring perfusion, renal parameters).
4. Digoxin should be given to patients with ventricular dysfunction and symptoms of stage C HF to relieve symptoms. Lower doses of digoxin are preferred for this purpose.
5. For treating moderate or severe left ventricular dysfunction, with or without symptoms (HF stages B and C), ACE inhibitors should be routinely used unless contraindicated. These medications should be started at low doses and titrated up to the maximal tolerated safe dose. Higher dosages of ACE inhibitors may require reducing the dose of diuretics.
6. In all cases of HF associated with structural heart disease (HF stages B, C, and D), surgical repair should be considered because long-term results may be better than those from medical management alone.
7. Clinical management of diastolic dysfunction should address symptoms and the underlying cause, if known. Management should include a careful search for pericardial disease and coronary insufficiency with attendant myocardial ischemia. Systemic hypertension, if present, should be aggressively treated.
8. Fluid management to control symptoms remains a cornerstone in treating symptomatic diastolic dysfunction (HF stage C). Diuretics can help control symptoms but must be used cautiously because cardiac output depends on increased filling pressures. Renal function should be followed closely to determine optimal doses. Restricting sodium and fluid intake may help control symptoms.
9. Atrial arrhythmias can occur in patients with diastolic dysfunction caused by atrial enlargement. However, atrial contribution to ventricular filling is particularly important for these patients (HF stages B and C). Therefore, if possible, sinus rhythm should be maintained with antiarrhythmic therapy and pacemakers.
10. Patients with diastolic dysfunction refractory to medical or surgical management should be evaluated for heart transplantation because the risk for pulmonary hypertension and sudden death is high (HF stage C).
11. Mechanical cardiac support should be considered in patients without structural congenital heart disease, who present with acute low cardiac output, or who have intractable arrhythmias during a presumably temporary condition that is refractory to medical therapy (HF stage D), such as myocarditis, septic shock, or acute rejection after heart transplantation.
12. Mechanical cardiac support should be considered in patients with or without structural congenital heart disease who have acute decompensation of end-stage HF, primarily as a bridge to heart transplantation (HF stage D).
13. In patients with marked arrhythmias and HF associated with structural heart disease (HF stages B, C, and D), surgical repair of uncorrected or residual defects should be considered because such repairs are likely to be essential for controlling arrhythmias.
14. In patients with marked arrhythmias and HF associated with structural heart disease (HF stages B, C, and D), medical treatment for HF should be optimized, and aggravating factors, such as electrolyte abnormalities, should be corrected because these actions are key to controlling arrhythmias.
15. In patients with marked arrhythmias and HF associated with structural heart disease (HF stages B, C, and D), maintaining atrioventricular synchrony is critically important to optimize hemodynamics, and intra-atrial arrhythmias should be managed to restore sinus rhythm, rather than solely to control ventricular rate.

ACE, Angiotensin-converting enzyme; HF, heart failure.

<sup>a</sup>All recommendations are class I recommendations, meaning that a given therapy is generally accepted as being useful and effective.

## Chapter 362

# HYPERTENSIVE EMERGENCIES

Srinivasan Suresh, MD, MBA; Usha Sethuraman, MD

Acute hypertensive emergencies are relatively infrequent in the pediatric population. However, their full clinical manifestations represent potential life-threatening events, demanding prompt identification and carefully implemented therapeutic intervention. The increasing array of potent oral and parenteral antihypertensive agents, as well as the widespread availability of dialysis, has resulted in marked reductions of morbidity and mortality associated with hypertensive crises. With the development of databases and the US Food and Drug Administration (FDA) Modernization Act in place (including endeavors such as the Best Pharmaceuticals for Children Act), studies for the evaluation and management of hypertension in children will be forthcoming.

Hypertensive crisis is classified into urgency and emergency. *Hypertensive emergency* is distinguished from *hypertensive urgency* by the presence of acute end-organ dysfunction discovered in the history, physical examination, or laboratory studies, and not from the child's blood pressure (BP). The division into these 2 categories determines where treatment should be administered: in the emergency department (ED), intensive care unit (ICU), or routine hospital unit. Classifying the hypertensive episode as *urgent* or *emergent* governs the approach to treatment. Although hypertensive urgencies develop over days to weeks, hypertensive emergencies may develop over hours.

*Malignant hypertension* is characterized by marked increases in systolic BP, diastolic BP, or both (eg,  $\geq 160$  mm Hg systolic and  $\geq 105$  mm Hg diastolic for children younger than 10 years;  $\geq 170$  mm Hg systolic and  $\geq 110$  mm Hg diastolic for children older than 10 years) and is often associated with spasm and tortuosity of the retinal arteries, papilledema, and hemorrhages and exudates on fundoscopic examination. Hypertensive encephalopathy (an example of hypertensive emergency), often seen in malignant hypertension, consists of a combination of signs and symptoms that may include nausea, vomiting, headaches, altered mental status, visual disturbances, seizures, and stroke.

## EVALUATION

As part of the initial physical assessment, all children evaluated for hypertension must have their BP measured in both upper extremities and in at least 1 lower extremity. When faced with newly diagnosed hypertension in the

child, the physician should determine: (1) Is the hypertension primary or secondary? (2) Does evidence exist of target organ injury? (3) Do associated risk factors exist?

## History

A brief but thorough history should be obtained with the goal of classifying the severity of the hypertension. Some key features in the history would be the duration and onset of hypertension, degree of adherence with any drug therapy, and possibility of renal disease. Therefore physicians should be alert to any history of urinary tract infections, failure to thrive, hematuria, edema, or umbilical artery catheterization. Physicians should also inquire about any history of joint pain, palpitations, weight loss, flushing, weakness, drug ingestion, headaches (including characterization), nausea, and vomiting and should ask about a family history of renal disease or hypertension.

## Physical Examination

With severe hypertension, this evaluation should progress only after the ABCs (airway, breathing, and circulation) of resuscitation have been accomplished. BP should be recorded several times. Improper cuff size can affect the diagnosis; thus taking BP with the properly sized cuff is important. By convention, an appropriate cuff size is one with an inflatable bladder width that is at least 40% of the arm circumference at a point midway between the olecranon and the acromion. For such a cuff to be the optimal size for an arm, the cuff bladder length should cover 80% to 100% of the circumference of the arm. BP measurements tend to be overestimated when a cuff is too small and underestimated when a cuff is too big. If a cuff is too small, then the next largest cuff should be used, even if it seems large.

A focused physical examination should immediately be performed, with a focus on checking for any evidence of neurologic dysfunction. Funduscopy should be performed to assess for hemorrhage, papilledema, or infarcts. Hepatomegaly, rales on chest auscultation, and edema suggest congestive heart failure. Any discrepancy in the upper and lower extremity BP measurements should be noted because this may indicate coarctation of aorta. Presence of an abdominal bruit suggests a renovascular cause of hypertension.

## Laboratory Evaluation

The laboratory and radiologic workup can then be divided into 3 categories: tests for diagnosis of primary or secondary hypertension, tests for target organ injury, and tests for associated risk factors (Box 362-1).

## MANAGEMENT

### Hypertensive Emergency

In children with hypertensive emergency, vascular access should be established immediately, and the patient should undergo cardiac and continuous BP monitoring, preferably by an intra-arterial catheter. Urine output should be monitored from the outset. Any serious complications must be managed simultaneously with the hypertension (eg, anticonvulsants should be administered to a patient experiencing seizures, along with hypertensive medications).

**BOX 362-1 Laboratory Tests for Hypertension****TESTS FOR DIAGNOSIS OF PRIMARY OR SECONDARY HYPERTENSION****Laboratory**

- Urinalysis
- Urine culture
- Urinary catecholamines
- Complete blood count with platelet count and blood smear
- Serum electrolytes, calcium, phosphorus
- Serum blood urea nitrogen, creatinine
- Serum C3 complement, antistreptolysin O titer, antinuclear antibody
- Plasma renin

**Radiology**

- Chest radiograph
- Intravenous pyelogram

- Voiding cystourethrogram
- Cardiac catheterization
- Renal ultrasound
- Renal scan
- Renal arteriogram

**Other**

- Electrocardiogram

**Tests for Target Organ Injury**

- Urinalysis
- Chest radiograph
- Electrocardiogram

**Tests for Associated Risk Factors**

- Serum lipid profile (eg, lipoprotein electrophoresis)
- Serum uric acid

Several medications are available for hypertensive emergencies (see Table 362-1). The drugs chosen depend on several factors, such as the child's clinical condition, the presumed cause, whether a change occurred in cardiac output or total peripheral resistance, and whether end-organ involvement is present. The goal is to lower the BP promptly but gradually because a sudden decrease in BP can lead to neurologic complications, such as intracranial bleeding. Hypertensive emergencies should be treated by an intravenous antihypertensive drug that produces a controlled reduction in the BP, with the aim of decreasing the pressure by 25% or less over the first 8 hours, then gradually normalizing the BP over 24 to 48 hours. Each of the most commonly used medications has advantages and disadvantages, and each clinical situation requires its own mode of management. However, some helpful general guidelines exist.

Labetalol is an  $\alpha_1$ - and nonselective  $\beta$ -adrenergic blocker. It has been reported to be effective in the management of severe hypertension that results from pheochromocytoma and coarctation of the aorta. Because dosing is independent of renal function, it is a reasonable alternative in the treatment of hypertensive crises in patients with end-stage renal disease.

Nicardipine is an excellent drug for use in emergencies because it can be administered as an easily prepared and titrated infusion.

Therapy with sodium nitroprusside, an arteriolar and venous vasodilator, is frequently effective. This drug works by reducing peripheral resistance and cardiac filling pressure. BP decreases with minimal change in cardiac output, and hence reflex tachycardia does not occur. The drug is administered by constant infusion, and the effects, which are seen quickly, last only as long as the infusion is continued. Use requires close observation, and therefore sodium nitroprusside may be inappropriate in the ED. Other disadvantages are that the drug requires 10 minutes

to prepare, is photosensitive, and is associated with a potential for cyanide accumulation.

Hydralazine is an arteriolar vasodilator that is not as potent as nitroprusside. However, it has an excellent safety profile. The half-life is short (3–7 hours); thus frequent dosing is required. Reflex tachycardia frequently occurs, necessitating the introduction of a beta blocker.

Esmolol is a selective  $\beta_1$  blocker that has been used in the treatment of postoperative hypertension following congenital heart disease repair. Experience with esmolol use outside of the postoperative setting is limited.

Phentolamine is a pure  $\alpha$ -adrenergic blocker used almost exclusively for the treatment of catecholamine crisis, as seen in patients with pheochromocytoma or in patients who ingested sympathomimetic agents such as cocaine. The effect is immediate. Phentolamine carries a high risk for hypotension after the primary lesion (eg, pheochromocytoma) is excised.

Nifedipine, a calcium channel blocker, reduces peripheral vascular resistance and does not affect cardiac output. It can be administered sublingually, but biting the capsule and swallowing its contents achieves blood levels more rapidly than administration by the sublingual route. Use depends on the patient's state of consciousness. Nifedipine is contraindicated in the presence of intracerebral bleeding.

Newer agents include fenoldopam and clevidipine. Fenoldopam reduces mean arterial pressure by vasodilation. Clevidipine is an ultra-short-acting dihydropyridine calcium channel antagonist that causes less tachycardia than nitroprusside. These properties make it a valuable drug in the management of hypertensive emergency in the ED.

Diazoxide, an arteriolar vasodilator, is no longer recommended for routine use.

**Hypertensive Urgency**

Patients with hypertensive urgency may not require hospitalization if the therapy in the ED is successful

**Table 362-1****Most Commonly Used Antihypertensive Agents for the Treatment of Hypertensive Urgencies and Emergencies in Children<sup>a,b</sup>**

DRUG	CLASS	ROUTE	DOSE	ONSET OF ACTION	DURATION OF ACTION
Labetalol	$\alpha_1$ , $\beta$ Blocker	IV	Bolus dosing: 0.2–1 mg/kg (max 40 mg/dose) Infusion: 0.25–3 mg/kg/hr IV	5–10 min	2–4 hr
Nicardipine	Calcium channel blocker	IV	1–3 mcg/kg/min	2–5 min	30–60 min
Sodium nitroprusside <sup>c</sup>	Direct vasodilator	IV	0.5–8 mcg/kg/min	Seconds	During infusion only
Hydralazine <sup>c</sup>	Direct vasodilator	IV/IM	0.1–0.6 mg/kg/dose (max 20 mg)	10–30 min	4–12 hr
Esmolol	$\beta_1$ Blocker	IV	Bolus 100–500 mcg over 1 min; 25–100 mcg/kg/min; can increase to 500 mcg/kg/min	Seconds	10–20 min
Phentolamine <sup>c</sup>	$\alpha$ Blocker	IV	0.1–0.2 mg/kg/dose; not to exceed 5 mg/dose (0.05–0.1 mg/kg/dose for treatment of hypertension during surgery)	Seconds	15–30 min
Fenoldopam <sup>c</sup>	Dopamine receptor agonist	IV	0.2–1.2 mcg/kg/min	5–15 min	1–4 hr
Nifedipine	Calcium channel blocker	Sublingual	0.1–0.25 mg/kg/dose (max 10 mg)	20–30 min	6 hr
Isradipine	Calcium channel blocker	PO	0.05–0.1 mg/kg/dose (max 5 mg)	30 min–2 hr	12 hr
Clonidine <sup>c</sup>	$\alpha_2$ -Receptor agonist	PO	0.05–0.3 mg	15–30 min	6–8 hr
Minoxidil <sup>c</sup>	Direct vasodilator	PO	0.1–0.2 mg/kg/dose (max 10 mg)	Within 1 hr	8–12 hr

ICP, intracranial pressure; IM, intramuscular; IV, intravenous; MAP, mean arterial pressure; PO, by mouth.

<sup>a</sup>Because several of these medications have not been extensively tested in children, existing pharmacokinetic data are frequently based on studies in adults.

<sup>b</sup>Dosing recommendations vary by source.

<sup>c</sup>Indicates drugs with US Food and Drug Administration–approved pediatric labeling for use in hypertension.

and if follow-up is adequate. In many instances, oral antihypertensive agents are sufficient, although parenteral therapy is sometimes indicated. Generally, one-third of the total planned BP reduction should be done during the first 6 hours, another third during the next 24 to 36 hours, and the final third during the next 24 to 96 hours or even longer. A 4- to 6-hour period of observation after the administration of the antihypertensive agent is recommended in the ED to identify any untoward effects of the medication. Patients should be discharged with the same medications that were used in the ED to treat the hypertension.

Results of pediatric studies of amlodipine, felodipine, isradipine, intravenous nicardipine, and nitrendipine have been published. Enalapril, an angiotensin-converting enzyme inhibitor, is commonly used as an antihypertensive agent in children. The maximal serum concentration occurs approximately 1 hour after administration, and that of its metabolite, enalaprilat, peaks 4 to 6 hours after the first dose and 3 to 4 hours after multiple doses. Amlodipine is a safe and effective antihypertensive drug in children with chronic renal disease. When administered in the ICU, intravenous

nicardipine is safe and effective in lowering the BP in children with severe hypertension.

### Malignant Hypertension

The urgency of prompt treatment of malignant hypertension is attested to by the fact that one-third of severely hypertensive children develop neurologic abnormalities that may be sudden in onset and leave permanent neurologic deficits. These abnormalities include cortical blindness, infarction of the optic nerve, and hemiplegias. Patients with malignant hypertension are usually admitted to an ICU for continuous cardiac monitoring and frequent assessment of neurologic status and urine output. An intravenous line is placed to permit administration of fluids and medications. Patients typically have altered BP autoregulation, and overzealous reduction of BP to reference range levels may result in organ hypoperfusion.

The initial goal of therapy is to reduce the mean arterial pressure by approximately 25% over the first 24 hours. An intra-arterial line is helpful for continuous titration of BP. Sodium and volume depletion may be severe, and volume expansion with isotonic sodium

chloride must be considered. No trials have been performed that compare the efficacy of various agents in the treatment of malignant hypertension in children. Drugs are chosen based on their rapidity of action, ease of use, special situations, and convention.

## PROGNOSIS

The immediate prognosis of the child who has symptoms resulting from a hypertensive emergency depends on the rapidity of recognition of the problem and achievement of appropriate BP reduction thereafter. Although the initial neurologic and visual disturbances may improve or resolve with time, risks remain for residual abnormalities such as seizure disorders, cranial nerve palsies, hemiplegia, and blindness. Renal function often deteriorates acutely in patients who have chronic renal disease after a hypertensive emergency or urgency. With sustained BP control, renal function may improve over a period of weeks or longer.

The long-term prognosis also depends on the underlying cause, as well as the effective management of the malignant hypertension. Some causes, such as acute poststreptococcal glomerulonephritis, may resolve on their own. Others, such as isolated vascular abnormalities, are amenable to correction. In other settings, such as hypertension associated with chronic glomerulonephritis, the condition may be controlled by continued antihypertensive therapy, although failure to adhere to medication regimens remains a problem. The development of end-organ damage (eg, hypertensive cardiomyopathy, stroke) is directly related to the adequacy of long-term BP control.

## CONCLUSION

Hypertensive emergencies in symptomatic children should be treated without delay to avoid further damage to vital organs. When treating children with hypertensive emergencies, BP should be brought down by no more than 25% within the first few hours. A pathogenesis for hypertension may be evident in individual cases, and management decisions must be made based on the cause of the hypertension.

### WHEN TO REFER

- Consultation with a pediatric nephrologist should be undertaken for diagnostic evaluation of the cause of the hypertension and short- and long-term management suggestions.
- Consultation with a pediatric cardiologist or pediatric neurologist should be undertaken if end-organ cardiac or central nervous system injury is suspected or if a question exists of the relationship between end-organ dysfunction and hypertension.

### WHEN TO ADMIT

- All hypertensive emergencies
- Most cases of hypertensive urgencies

## Chapter 363 HYPOGLYCEMIA

Srinivasan Suresh, MD, MBA; Indumathi Santhanam, MD, DCH

## INTRODUCTION

Any acutely ill child should be evaluated for hypoglycemia, especially when the history reveals diminished oral intake. Diagnosing hypoglycemia promptly is essential because low blood glucose levels that persist or recur may have catastrophic effects on the brain, particularly in infants. Accordingly, the primary care physician must recognize the clinical symptoms associated with hypoglycemia, document the low blood glucose level, and treat appropriately with glucose. Delineating the cause of the hypoglycemia is necessary to initiate effective continuing treatment.

## DEFINITIONS

A child who has a serum or plasma glucose concentration less than 40 mg/dL or a whole blood glucose concentration less than 35 mg/dL should be investigated and treated for hypoglycemia; those who have plasma glucose concentrations between 40 and 50 mg/dL should be followed carefully. On the basis of observational data and expert opinion, the World Health Organization (WHO) currently provides different definitions for different specific clinical categories: newborns and infants with “signs of illness” (<45 mg/dL), healthy term or preterm newborns “feeding well” (<19.8 mg/dL), and

infants and children with severe malnutrition (54 mg/dL). If hypoglycemia is suspected, then the blood glucose level may be approximated quickly at the bedside using a visual test strip or glucose meter and later confirmed by an appropriate chemical laboratory test. Although these thresholds have been commonly quoted and used, the level of plasma glucose that is safe is uncertain, and some authorities advocate a therapeutic goal of maintaining a plasma glucose level above 60 mg/dL in both neonates and older children to prevent permanent brain damage.

## CLINICAL MANIFESTATIONS

The clinical findings in hypoglycemia are those caused mainly by cerebral dysfunction and adrenergic discharge. Incoordination of eye movements, strabismus, excessive irritability, motor incoordination, and convulsions may occur after 1 month of age. In the older child, pallor, tachycardia, sweating, limpness, inattention, staring, listlessness, hunger, abdominal pain, ataxia, stupor, coma, and convulsions are frequent findings. Episodes of hypoglycemia may be present at any age without obvious clinical manifestations.

## ETIOLOGY

The blood glucose level is the final balance between the sum of hepatic glucose production and dietary intake minus peripheral glucose use. An adequate fasting blood glucose concentration depends on sufficient amounts of endogenous nonglucose precursors (eg, alanine, lactate, glycerol), effective hepatic enzyme pathways for gluconeogenesis and glycogenolysis, and normal hormonal activities (insulin, growth hormone [GH], cortisol, glucagon, and epinephrine) for the mobilization of substrates and the regulation of these processes.

## INCIDENCE

The overall incidence of symptomatic hypoglycemia in newborns varies from 1.3 to 3 per 1,000 live births. Early feeding decreases the incidence of hypoglycemia. Prematurity, hypothermia, hypoxia, maternal diabetes, maternal glucose infusion in labor, and intrauterine growth restriction increase the incidence of hypoglycemia.

## DIFFERENTIAL DIAGNOSIS

Metabolic acidosis, ketonemia, or hepatomegaly in association with hypoglycemia strongly suggests the presence of an inborn error of metabolism of carbohydrate, amino acid, or organic acid. Hypotonia and hyperammonemia may also be present in infants who have defects in organic acid and amino acid metabolism. The presence of non-glucose-reducing substances in the urine may indicate galactosemia or hereditary fructose intolerance (HFI). Nonketotic hypoglycemia in patients who have hepatomegaly, with or without metabolic acidosis, suggests 3-hydroxy-3-methylglutaric aciduria, glutaric aciduria type II, systemic carnitine deficiency, carnitine palmityl transferase deficiency, or long- and medium-chain acyl-coenzyme A dehydrogenase (MCAD) deficiencies. In contrast, hepatomegaly, ketonuria, and metabolic acidosis are usually absent in patients with hypoglycemia accompanied by hyperinsulinism. The findings of ketonuria and hypoglycemia without hepatomegaly

among small and underweight boys older than 1 year suggest ketotic hypoglycemia, although ketosis may be present in some hypoglycemic patients who have hypopituitarism and adrenocorticotrophic hormone (ACTH) unresponsiveness.

## Hyperinsulinism

Hyperinsulinism may be caused by any of several abnormalities of the  $\beta$  cell (Box 363-1) and is the most common cause of persistent or recurrent hypoglycemia in the first year of life. In Beckwith-Wiedemann syndrome (omphalocele, macroglossia, and gigantism), hypoglycemia occurs in many of the affected infants and resolves at several months of age. Some of these infants also have hemihypertrophy. An increased incidence of adrenal, liver, and kidney (Wilms) tumors occurs in these patients. More commonly, hyperinsulinism is transient and associated with infants of diabetic mothers.

Most children who have hypoglycemia caused by persistent hyperinsulinism (previously called *nesidioblastosis*, *islet cell dysplasia*, or *congenital hyperinsulinism*) have symptoms beginning during the first year of life. The understanding of the genetic basis of this condition has advanced enormously in the past several years. Pancreatic  $\beta$ -cell insulin secretion is regulated through a multistep signaling pathway. Glucose, amino acids, and other fuels are metabolized in the  $\beta$  cells, raising the ratio of adenosine triphosphatase to adenosine diphosphate. This action, in turn, activates a plasma protein, the sulfonylurea receptor (SUR), to close a potassium channel ( $K_{ATP}$ ), depolarizing the membrane and leading to an influx of calcium and release of insulin. The rate-limiting step in glucose metabolism is the enzyme glucokinase. The most severe form of congenital hyperinsulinism has been found to be caused by a recessive mutation in the  $K_{ATP}$ . Other forms of congenital hyperinsulinism are caused by mutations in the SUR, potassium pore, glucokinase, and other steps of the signaling path. Congenital hyperinsulinism seems to occur in association with either focal or diffuse abnormalities of the  $\beta$  cells.

Pancreatic islet cell adenomas are uncommon in children. Although hypoglycemia caused by varying histologic types of insulinoma may have its onset in the newborn period, symptoms begin after the age of 4 years in 85% of patients.

## Inborn Errors of Metabolism

### Carbohydrate Enzyme Defects

Several enzymatic defects of carbohydrate metabolism result in deficiencies of hepatic glucose formation and release. Glucose-6-phosphatase deficiency is the most common deficiency, and the symptoms are more severe than those in other glycogen storage disease (GSD) types (see Box 363-1). Patients who have GSD types 1a and 1b have growth restriction, cherubic facies, a protuberant abdomen, a large smooth liver, enlarged kidneys, normal intelligence, fasting hypoglycemia of only a few hours' duration, ketosis, lactic acidemia, hyperlipidemia, hyperuricemia, and bleeding diathesis. In type 1b, the patients also have neutropenia and an increased frequency of infections. Among infants and young children, poor food intake during an

**BOX 363-1 Causes of Hypoglycemia in Childhood<sup>a</sup>****HYPERINSULINISM**

- Islet cell dysplasia (functional  $\beta$ -cell secretory disorder)
- Islet cell adenoma
- Adenomatosis
- Beckwith-Wiedemann syndrome

**HEREDITARY DEFECTS IN CARBOHYDRATE METABOLISM**

- Glycogen storage diseases
- Glucose-6-phosphatase deficiency types Ia and Ib
- Amylo-1,6-glucosidase deficiency type III
- Defects of liver phosphorylase enzyme system

**ENZYME DEFICIENCIES OF GLUCONEOGENESIS**

- Fructose-1,6-diphosphatase
- Phosphoenolpyruvate carboxykinase
- Pyruvate carboxylase

**OTHER ENZYME DEFECTS**

- Galactose-1-phosphate uridyltransferase (galactosemia)
- Fructose-1-phosphate aldolase (hereditary fructose intolerance)
- Glycogen synthetase

**HEREDITARY DEFECTS IN AMINO ACID AND ORGANIC ACID METABOLISM**

- Maple syrup urine disease
- Propionic acidemia
- Methylmalonic aciduria
- Tyrosinosis
- 3-Hydroxy-3-methylglutaric aciduria
- Glutaric aciduria type II

**HEREDITARY DEFECTS IN FAT METABOLISM**

- Systemic carnitine deficiency
- Carnitine palmitoyl transferase deficiency
- Long- and medium-chain acyl-coenzyme A dehydrogenase deficiencies

**HORMONE DEFICIENCIES**

- Congenital hypopituitarism or hypothalamic abnormality

- Growth hormone
- Cortisol
- Adrenocorticotrophic hormone (ACTH)
- ACTH unresponsiveness
- Glucagon
- Thyroid hormone
- Catecholamine

illness may result in severe lactic acidosis and hypoglycemia. Death may result if hypoglycemia and lactic acidemia are not treated adequately and promptly with intravenous glucose and sodium bicarbonate.

**Reye Syndrome**

Because children who have an inborn error of metabolism may exhibit a Reye syndrome–like illness, the primary care physician must be alert to the possibility

of an underlying metabolic defect, particularly in young children or in a child who has a recurrence of Reye syndrome–like symptoms.

**Galactosemia**

Galactosemia in a lactose-fed infant is characterized by failure to thrive, jaundice, vomiting, susceptibility to infection, hepatomegaly, edema, ascites, a tendency to bleed, cataracts, proteinuria, aminoaciduria, and

New York, NY: Elsevier; 1980.

galactosuria. Intellectual disability, progressive liver failure, and death may occur unless galactose-containing feedings are eliminated. Symptomatic hypoglycemia is not a common finding and is reversed quickly by intravenous glucose.

### **Hereditary Fructose Intolerance**

Clinical manifestations of hereditary fructose intolerance (HFI) develop only after fructose ingestion and include vomiting, profound hypoglycemia, and convulsions. Continued ingestion of fructose is associated with failure to thrive, prolonged vomiting, jaundice, hepatosplenomegaly, hemorrhage, abnormal liver function, fructosuria, defects in proximal renal tubular function (including proteinuria, glucosuria, and aminoaciduria), and, in some cases, hepatic failure and death.

### **Fructose-1,6-Diphosphatase Deficiency**

Patients who have fructose-1,6-diphosphatase (FD-Pase) deficiency may have episodic hyperventilation, fasting hypoglycemia, lactic acidosis, ketosis, hyperuricemia, and hepatomegaly. Refusal to eat and vomiting, often associated with febrile illness, precipitate the attacks. The disorder is life threatening in neonates and in young children. In contrast to those who have HFI, these patients do not vomit after fructose intake and do not develop an aversion to sweets.

### **Amino Acid and Organic Acid Metabolic Defects**

Hypoglycemia has been noted in a variety of inborn errors of amino acid and organic acid metabolism (see Box 363-1). Although symptoms usually begin in the neonatal period, they may occur later. The infants tend to improve when protein feedings are discontinued and glucose is administered intravenously. Occasionally, peritoneal dialysis or exchange transfusion may be life-saving. Amino acid analysis and gas chromatography of blood and urine are often helpful in detecting these inborn errors (Table 363-1). Diagnosis and treatment of a specific disorder depend on detection of its characteristic metabolites in blood and urine and on assays of specific enzyme activities in skin fibroblasts or white blood cells.

The most common defect of fatty acid oxidation is medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. This condition may exhibit as nonketotic hypoglycemia (similar to Reye syndrome), an acute life-threatening event, or even sudden death. In fact, an association has been made between infants with known MCAD deficiency and a history of a sibling dying of sudden infant death syndrome. Initial screening for defects of fatty acid oxidation is best performed with analysis of urine organic acids, plasma acylcarnitine profile, and measurement of serum carnitine.

### Hormonal Deficiencies

Growth hormone deficiency, cortisol deficiency, or combined hormonal deficiencies may cause hypoglycemia.

#### Hypopituitarism

Congenital hypopituitarism, caused by either a hypothalamic abnormality or aplasia of the anterior pituitary gland, is associated with severe hypoglycemia during the first few days of life. Occasionally, however, hypoglycemia may first appear later in infancy or childhood. A few patients may have midline deformities, including hypotelorism, abnormality of the frontonasal process, and cleft lip or palate. Septo-optic dysplasia (optic nerve hypoplasia and absence of the septum pellucidum) is present in some patients and may be accompanied by nystagmus. Some male patients who have congenital hypopituitarism may have a small penis (microphallus) or genitalia, and children with hypopituitarism are often overweight. Measurement of height and weight is essential for the evaluation of a child in whom GH deficiency is suspected because these children have significant growth restriction, which may begin within the first 1 to 2 years of life.

#### Cortisol Deficiency

Deficient cortisol production may be caused by Addison disease, congenital adrenal hyperplasia, adrenocorticotrophic hormone (ACTH) deficiency, or ACTH unresponsiveness. Patients who have ACTH unresponsiveness and Addison disease may have abnormal pigmentation.

### Ketotic Hypoglycemia

Although the pathogenesis of hypoglycemia in ketotic hypoglycemia has not been defined, the evidence suggests that it represents an exaggeration of the starvation state. During hypoglycemia, blood insulin levels are appropriately low; blood alanine levels also may be low; GH, glucagon, cortisol,  $\beta$ -hydroxybutyrate, and free fatty acid levels in the blood are elevated; urinary ketones are present; and blood glucose levels fail to rise after the administration of glucagon.

Ketotic hypoglycemia is the most common cause of hypoglycemia after 1 year of age. Symptoms mimicking those noted in ketotic hypoglycemia have occurred in children who have GH deficiency, ACTH unresponsiveness, FDPase deficiency, glycogen synthetase deficiency, and Reye syndrome. Before a child is classified as having ketotic hypoglycemia, therefore, a thorough laboratory investigation must be conducted to consider these and other diseases.

The combination of ketonuria, hypoglycemia, and central nervous system symptoms, which may vary from unresponsiveness, pallor, and vomiting to coma and convulsions and which often occur in the early morning hours in association with an upper respiratory tract infection or prolonged fast, is typical of ketotic hypoglycemia for which no cause is known. The onset is between 9 months and 5.5 years of age, with a peak incidence at 2 years. Hypoglycemic episodes occur at intervals of a few months to a year or more; they then decrease in frequency and tend to disappear, usually by 7 to 8 years of age.

### EVALUATION

Hypoglycemia reflects the failure of 1 or more factors that regulate the concentration of glucose in the blood (see Box 363-1). Clinical clues enable the physician to plan a logical approach to the diagnostic evaluation of a patient who has hypoglycemia. The age at onset of hypoglycemia is important. The inborn errors of carbohydrate, amino acid, organic acid metabolism, and hormonal deficiencies become apparent during the first 2 years of life. Hyperinsulinism has 2 peak times of onset: during the first year of life and after the age of 3 years. Ketotic hypoglycemia is the most likely cause of hypoglycemia with onset after 1 year of age. In toddlers, hypoglycemia may result from ingestion of alcohol, aspirin, and other drugs (see Box 363-1). Hypoglycemia is rare after the age of 5 years.

#### History

A history of other affected family members or the occurrence of unexplained infant deaths among close relatives suggests the possibility of an inherited metabolic disorder. Some disorders associated with hormonal deficiencies and hyperinsulinism also may be familial. The physician should inquire about the frequency of hypoglycemic episodes, the possibility of drug ingestion, and the malicious administration of drugs. The temporal relationship of symptoms to food intake is important in assessing for hypoglycemia. In hereditary defects of amino acid and organic acid metabolism, hypoglycemic symptoms may occur shortly after the ingestion of protein. Symptoms that occur after the ingestion of lactose suggest galactosemia; those that occur after sucrose ingestion suggest HFI. In contrast, fasting hypoglycemia is characteristic of ketotic hypoglycemia, hormonal deficiencies, hyperinsulinism, GSD, and FDPase deficiency (see Table 363-1).

#### Laboratory Evaluation

At the time hypoglycemia is suspected in a child, a diagnostic blood sample for glucose, insulin, GH, cortisol, ketone bodies, lactic acid, and amino acids must be obtained, generally before the low blood glucose level has been corrected. These measurements provide important information concerning cause. Unnecessary blood sampling can be minimized by using a bedside glucose meter to decide if the patient is truly hypoglycemic during a symptomatic episode. If available blood volume is a limiting factor, then judgment must be used in ranking the importance of these tests, with measurement of the blood glucose and insulin levels receiving priority. Urinary ketones, as well as specific tests for urinary glucose and non-glucose-reducing substances, should also be determined. If ketones are present, then the urine should be tested further for presence of amino acids and organic acids. For diagnostic purposes, the administration of glucagon can be useful; a robust glycemic response to glucagon strongly suggests hyperinsulinism.

### Diagnostic Evaluation for Specific Disorders

#### Hyperinsulinism

Hyperinsulinism in infants and older children is usually characterized by fasting hypoglycemia, even if of only a

few hours' duration, and low fasting plasma levels of  $\beta$ -hydroxybutyrate and free fatty acids. Frequent random simultaneous measurements of blood glucose and insulin levels, particularly before feeding and as hypoglycemia occurs, help identify patients who have hyperinsulinism (see Table 363-1). The diagnosis depends on detecting inappropriate insulin secretion by demonstrating insulin levels disproportionately high relative to blood glucose values, particularly during hypoglycemia. A high rate of glucose infusion ( $>12$  mg/kg/min) is often necessary to maintain euglycemia. Leucine or tolbutamide challenges are not helpful in delineating the specific cause of hyperinsulinism.

In any child who has intermittent attacks of non-ketotic hypoglycemia, the physician should always investigate the possibility of malicious or self-administration of insulin or oral sulfonylurea drugs. Measurement of C-peptide, insulin, and insulin antibodies in blood may identify the patient who has an exogenous source of insulin. In contrast to patients who have endogenous hyperinsulinism, C-peptide levels are suppressed; insulin antibodies may be present in patients to whom insulin has been administered. In children who have received oral hypoglycemic agents, plasma insulin and C-peptide levels may be misleading; however, the drug may be detected in the child's blood or urine.

### Inborn Errors of Metabolism

A suggested outline for the investigation of hypoglycemia caused by inborn errors of carbohydrate

metabolism is provided in Table 363-1 and Table 363-2. These studies should be performed in a pediatric metabolic center but only when the child's condition is stable and the blood glucose level is normal. Judgment must be exercised in choosing the proper diagnostic test to delineate the underlying abnormality. The presence of specific hepatic enzyme deficiencies may be determined by the use of other tolerance tests (see Table 363-2). The tolerance tests are performed after a variable period of fasting and only with a primary care physician in attendance, who must be prepared to interrupt the test by administering intravenous glucose should symptoms and signs of hypoglycemia occur or should a low blood glucose level be detected. Definitive diagnosis of any of the inherited disorders of carbohydrate metabolism (see Box 363-1) except galactosemia depends on assay of specific hepatic enzyme activities (see Table 363-2). Galactosemia, on the other hand, may be detected by the absence of galactose-1-phosphate uridylyltransferase activity in red blood cells; thus liver biopsy is unnecessary for its definitive diagnosis.

### Hormone Deficiencies

Laboratory studies should include determination of GH and cortisol in the blood, particularly when the child has hypoglycemia (see Table 363-1). Hypoglycemia is an excellent stimulus for GH and cortisol secretions; therefore low values of either hormone in the presence of hypoglycemia raise suspicion of deficiencies of these hormones and the need for further studies. In patients

who have suspected hypopituitarism or GH deficiency, magnetic resonance imaging and computed tomography of the brain may be of diagnostic help. Correction of hypoglycemia by intravenous administration of glucose makes up the treatment of acute episodes. Specific treatment depends on identifying the underlying hormonal deficiency. However, if GH or cortisol deficiency is suspected on clinical grounds, then empirical replacement therapy should be started while awaiting test results. Patients should be encouraged to avoid prolonged fasting.

## MANAGEMENT

Healthy, full-term infants are functionally and metabolically programmed to make the transition from their intrauterine-dependent environment to their extrauterine existence without the need for metabolic monitoring. Full-term infants are equipped with homeostatic mechanisms that preserve adequate energy substrate to the brain and other vital organs. Thus routine newborn screening for blood glucose concentration is not necessary. Glucose water supplement should not be given to breastfeeding newborn infants unless a medical indication exists. However, many healthy infants and young children, in contrast to adults, cannot maintain normoglycemia during a 24-hour fast. The glycogen stores of healthy infants are sufficient only to meet glucose requirements for 8 to 12 hours in the absence of caloric intake; therefore after 24 to 36 hours of fasting, the young child depends totally on gluconeogenesis for glucose production. Because of relatively lower protein and fat stores, fasting infants and young children may not be able to supply sufficient substrates for adequate glucose production. Hence the primary care physician caring for a child requiring surgery or other procedures accompanied by fasting must prevent hypoglycemia by ensuring that extended fasting is avoided, by administering parenteral glucose before and after surgery, and by monitoring the patient's blood glucose level.

### Immediate Management

After appropriate laboratory tests are sent, hypoglycemia should be corrected by administering 2 to 4 mL/kg of 10% to 25% glucose intravenously. Intravenous fluids containing appropriate electrolytes and glucose should be given at a rate sufficient to maintain plasma or serum glucose levels above 50 to 60 mg/dL. A common mistake is to think that the hypoglycemia resolved after the initial bolus and failing to follow up with sufficiently frequent blood glucose monitoring to determine the adequacy of the continuous glucose infusion. The blood glucose level should be monitored initially every 30 to 60 minutes at the bedside until stable, then every 2 to 4 hours, and the rate of glucose administered should be adjusted accordingly. Overcorrection with subsequent hyperglycemia may complicate fluid management by causing an osmotic diuresis. In term healthy neonates, biochemical "hypoglycemia" is treated with early frequent sucking and skin-to-skin contact (kangaroo care). This was found effective in maintaining body temperature and safe blood glucose levels with no need for supplemental feeds.

Significant hypoglycemia should be evaluated on an inpatient basis to allow for close monitoring. During transport to the hospital, personnel experienced in intravenous techniques and rapid bedside blood glucose determinations must ensure that adequate amounts of glucose are infused continuously. The previously obtained diagnostic blood samples should be sent with the patient to the hospital, preferably on ice. The child who has hypoglycemia should be under the combined care of a pediatric specialist and primary care physician.

### Hyperinsulinism

Patients with hyperinsulinism require a higher rate of glucose infusion ( $>12$  to  $14$  mg/kg/min) to maintain a normal blood glucose level compared with other conditions causing hypoglycemia. The further management depends on the age at onset of the condition.

### Diazoxide

An infant's response to diazoxide is of great diagnostic and therapeutic value in hyperinsulinism. Diazoxide raises blood glucose levels primarily by suppressing pancreatic insulin secretion. In patients in whom diazoxide results in restoration of normal glucose levels, use of the drug is continued, and the patients are assessed periodically until approximately 5 to 7 years of age. Some patients remain euglycemic without medication by this age. The knowledge that many of these patients harbor genetic defects supports the concept that although clinical improvement may occur with increasing age, abnormalities of glucose regulation remain. Because hyperglycemia, ketosis, and hyperosmolar nonketotic coma can occur with diazoxide therapy, the parents should be instructed to monitor urinary glucose and ketones.

Diazoxide acts by inhibiting the  $\beta$ -cell SUR. Although it is effective in many children, hyperinsulinism caused by SUR mutations may not respond to this drug. If hypoglycemia associated with hyperinsulinism persists or recurs despite diazoxide therapy, then octreotide, a long-acting analog of somatostatin, may be used. Tachyphylaxis has prevented its long-term use in all but a small number of severely affected children.

### Surgery

Congenital hyperinsulinism of infancy (CHI) is characterized by inappropriate insulin secretion resulting in persistent hypoglycemia, which can lead to irreversible severe neurologic damage in the infant. Most patients with CHI respond to medical therapy. Surgery is needed if medical therapy fails. Surgical strategies vary, depending on whether the disease is focal or diffuse. Near-total pancreatectomy is the procedure of choice for diffuse CHI, whereas a localized resection is curative in focal CHI. Open surgery is the traditional approach to pancreatic resection. However, laparoscopy is increasingly used, particularly in localized resection for focal disease.

### Carbohydrate Enzyme Defects

In treating carbohydrate enzyme defects, a significant advance has been the introduction of continuous nocturnal glucose-containing gastric feedings. To maintain

normal blood glucose levels during the day, frequent feedings, at least every 3 to 4 hours, are essential. Foods rich in fructose and galactose should be avoided. The daily oral administration of an uncooked cornstarch suspension has been beneficial in older children but not as effective in infants in maintaining normoglycemia and attaining adequate metabolic control.

### Galactosemia

When the diagnosis of galactosemia is suspected, the patient should be given a galactose-free diet immediately. This diet should be maintained carefully while the primary care physician awaits the results of erythrocyte enzyme studies and should be continued if the diagnosis is confirmed. Long-term management consists of avoidance of lactose- and galactose-containing foods.

### Hereditary Fructose Intolerance

The acute episodes of hypoglycemia are reversed promptly by the intravenous administration of glucose. Long-term treatment consists of strict elimination of dietary fructose and of fructose in cough syrups and other drugs.

### Fructose-1,6-Diphosphatase Deficiency

Treatment of acute attacks of FDPase deficiency consists of correcting the hypoglycemia and acidosis by intravenous infusion of glucose and sodium bicarbonate. Long-term management should emphasize the avoidance of fasting and the provision of a fructose-free, high-carbohydrate diet.

### Ketotic Hypoglycemia

In patients with ketotic hypoglycemia, the primary care physician should document hypoglycemic blood glucose levels at the time of symptoms by obtaining a diagnostic blood sample. After the child has had several days to recover from the acute episode and is eating well, the administration of a provocative low-calorie, high-fat ketogenic diet has been useful in establishing the diagnosis if a blood sample is unobtainable. The child must be observed carefully for hypoglycemia during the test period.

The acute hypoglycemic attacks are reversed by the intravenous administration of glucose; glucagon usually has no effect. Because the attacks occur infrequently, long-term drug therapy is not indicated. A liberal carbohydrate diet, including a bedtime snack, should be followed. Prolonged overnight fasting, particularly during weekends or holidays and periods of illness, should be avoided. The parents should be encouraged to test their child's urine for ketones during illness or periods of fasting. Carbohydrate-containing foods, given promptly when acetonuria develops, are usually successful in aborting attacks.

### WHEN TO ADMIT

- Any child with documented hypoglycemia not caused by insulin therapy should be hospitalized for careful monitoring and diagnostic testing. These patients need to be referred to an endocrinologist.

- If hypoglycemia is diagnosed in an infant younger than 3 months, then surgical intervention may be necessary. Surgical exploration is usually performed in severely affected neonates who are unresponsive to glucose and somatostatin therapy.

## Chapter 364

# INCREASED INTRACRANIAL PRESSURE

M. Mohsin Shah, MD; Matthew D. Smyth, MD

Elevated intracranial pressure (ICP) is a potentially life-threatening neurologic or neurosurgical emergency. Rapidly identifying and managing the cause can prevent serious morbidity and possible mortality. Elevated ICP has many causes, and symptoms can be acute, subacute, or chronic.

### PATHOPHYSIOLOGIC CONSIDERATIONS

The skull in older children and adults is closed and rigid and filled with 3 compartments—the brain (80%–90% of the volume), circulating cerebrospinal fluid (CSF; 5%–10% of the volume), and circulating blood (remainder of the volume). The Monro-Kellie doctrine dictates the pathophysiologic relationship of these compartments when altered. Based on this dictum that the relative volume is fixed, small increases in any of these compartments will result in a compensatory decrease in the others. ICP rises if the increase exceeds normal compensatory mechanisms. Also affecting this variable is the brain's compliance (stiffness), which is altered in various disease states. Changes in brain compliance dampen compensatory mechanisms because the brain accounts for most of the intracranial volume.

Normal ICP in older children and adults is usually 7 to 15 mm Hg in the recumbent position, and is lower in young children. ICP is pulsatile and varies around a baseline; variation results from cardiac and respiratory activity. Transient increases of up to 50 mm Hg or higher normally occur with actions that increase intrathoracic pressure or that impede venous return, such as coughing, sneezing, and straining. However, ICP returns rapidly to baseline when these actions are discontinued.

Under normal conditions, blood flow to the brain is autoregulated, maintaining a constant perfusion level

over a range of blood pressures. A disruption in autoregulation makes blood flow pressure passive, which, in turn, can lead to significant changes in cerebral perfusion with any change in blood pressure. The cerebral perfusion pressure (CPP) is the mean arterial pressure minus the ICP. CPP falls when ICP increases, leading to further cerebral compromise, ischemia, swelling, and further increases in ICP. This cycle may persist and ultimately cause death if not treated.

## ETIOLOGY

Many factors can cause increased ICP in children, which can be classified as shown in Box 364-1. Depending on the cause, intracranial hypertension can be chronic (as with pseudotumor cerebri) or acute (as with head trauma resulting in cerebral edema or intracerebral hemorrhage). Common causes of increased ICP in children include head trauma, infection, hydrocephalus, and mass lesions.

In idiopathic intracranial hypertension (pseudotumor cerebri), the mechanism is less clear, but, based on experimental data, is thought to be derived from 2 primary mechanisms—vasogenic extracellular brain edema and delayed reabsorption through the arachnoid villa. Idiopathic intracranial hypertension may be compounded by secondary exacerbation of intracranial venous sinus compression that results in further reduction of flow across the arachnoid villi. This condition predominantly affects young, obese women of childbearing age. Among young women of childbearing age, risk factors include the following:

1. Medications (vitamin A in infants, isotretinoin [Accutane], corticosteroids, all-trans-retinoic acid for treatment of promyelocytic leukemia, levothyroxine, tetracycline, trimethoprim-sulfamethoxazole, cimetidine, nalidixic acid, nitrofurantoin, recombinant growth hormone)
2. Endocrinopathies (recent weight gain, menstrual irregularity, adrenal insufficiency, Cushing disease, hypoparathyroidism, hypothyroidism, and excessive thyroxine replacement)
3. Chronic renal failure
4. Systemic lupus erythematosus

## SIGNS AND SYMPTOMS

Signs and symptoms of both acute and chronic increased ICP are presented in Box 364-2. Many of these are the same between the acute and chronic forms, demonstrating their somewhat nonspecific nature. The temporal pace of development differs between the 2 forms. Acute signs of rapidly increasing ICP result from displaced neuronal tissue through the several dural openings, with subsequent compression and ischemic changes to the cerebral structures. For example, with uncus herniation in association with supratentorial masses, the uncus is displaced through the tentorial opening, leading to compression of the ipsilateral third nerve and displacement of the peduncles and brainstem laterally (Figure 364-1). Clinically, the patient is comatose and has an ipsilateral pupillary dilation (third nerve palsy) and ipsilateral hemiparesis, which suggests a falsely localizing lesion in the contralateral hemisphere. The pupil reliably

### BOX 364-1 Causes of Increased Intracranial Pressure in Children

#### HEAD TRAUMA

- Cerebral edema
- Intracerebral hemorrhage
- Extracerebral hemorrhage (subdural, epidural)

#### VASCULAR CAUSES

- Arterial or venous infarctions
- Intracerebral hemorrhage
- Dural sinus thrombosis
- Subarachnoid hemorrhage
- Vascular anomalies (vein of Galen malformation, arteriovenous malformations)

#### NEOPLASTIC CAUSES

- Primary brain tumors
- Metastatic (intracerebral, meningeal infiltration)
- Hydrocephalus (congenital or acquired, communicating or noncommunicating)
- Pseudotumor cerebri (benign intracranial hypertension)
- Central nervous system infections
- Meningitis (bacterial, fungal, mycobacterial)
- Encephalitis (focal or diffuse)
- Abscess

#### METABOLIC CAUSES

- Inborn errors of metabolism (hyperammonemia)
- Hepatic encephalopathy
- Diabetic ketoacidosis
- Renal failure
- Reye syndrome
- Status epilepticus
- Hypoxic-ischemic encephalopathy
- Fluid-electrolyte abnormalities (hyponatremia, hypernatremia)

#### STRUCTURAL CAUSES

- Craniosynostosis

localizes the side of the lesion. Downward herniation of the cerebellar tonsils through the foramen magnum leads to compression and vascular compromise of the lower brainstem structures (medulla) (see Figure 364-1). Patients are comatose and exhibit decorticate or decerebrate rigidity and autonomic (respiratory and circulatory) changes. The symptoms of a widened pulse pressure, bradycardia, and deep, slow respiration are classically referred to as the *Cushing triad*. Clinically, this triad is rarely seen.

## DIAGNOSIS

The key to managing increased ICP is rapidly recognizing intracranial hypertension in a patient. As with

### BOX 364-2 Symptoms and Signs of Acute and Chronic Increased Intracranial Pressure in Children

#### INFANTS

##### Acute

- Irritability
- Poor feeding or emesis
- Split sutures (especially lambdoidal)
- Bulging fontanelle
- Altered mental status
- Seizures
- Parinaud sign (upgaze paresis)

##### Chronic

- Irritability
- Poor feeding or emesis
- Increased head circumference
- Bulging fontanelle
- Split sutures (especially lambdoidal)
- Apparent developmental arrest or regression
- Parinaud sign (upgaze paresis)

#### CHILDREN

##### Acute

- Severe, acute headache
- Seizures

- Emesis
- Rapidly deteriorating mental status
- Decerebrate or decorticate posture
- Focal neurologic deficits
- Papilledema
- Pupillary abnormalities
- Autonomic dysfunction (Cushing triad)

##### Chronic

- Chronic, progressive headache
- Seizures
- Early morning emesis
- Change in school performance
- Altered mental status
- Cranial neuropathy (eg, sixth cranial nerve palsy)
- Focal neurologic deficits
- Papilledema
- Visual changes

**Figure 364-1** Two sections from a computed tomography scan of a 5-year-old girl who is comatose and has increased intracranial pressure. **A**, Large, cystic left temporal lobe mass (*large arrow*) causing left uncus herniation (*small arrow*) with loss of perimesencephalic cistern and midline shift. **B**, A lower cut demonstrating loss of the fourth ventricle (*large arrow*) and a quadrigeminal cistern (*small arrows*), suggesting downward (tonsillar) herniation.

any individual with neurologic complaints, the history and physical and neurologic examinations are the most important aspects of the initial diagnostic evaluation. These examinations provide the physician with information on the pace of the illness, which allows the physician to discern the need for urgent versus emergent management. If a rapidly evolving process (eg, impending herniation) is evident, then stabilizing the patient is essential before proceeding to definitive diagnosis and therapy.

Performing a lumbar puncture (LP) provides an opportunity to evaluate the ICP by inserting a spinal needle into the thecal sac, attaching a manometer, and measuring the CSF column height while the patient is in the lateral decubitus position with legs extended. CSF opening pressures obtained during LP in this fashion correlate with ICP. It is important to note that instant measures of CSF pressure in a fluid column may be misleading because of its dynamic nature; measurement should, therefore, be averaged over 30 minutes. Opening pressures may also be influenced by age, body mass index (BMI), and depth of sedation. Normal opening CSF pressures range from 12 to 28 cm of water. However, if a mass lesion is suspected, then withdrawing lumbar CSF may create a pressure gradient intracranially and precipitate a herniation syndrome; therefore, neuroimaging is generally recommended before an LP. The lone exception is in children suspected of having meningitis, in which case neuroimaging before an LP may unnecessarily delay antibiotic treatment. If meningitis is a serious consideration and a computed tomography (CT) scan is still desired, then antibiotic therapy should not be delayed pending completion of the CT scan and, in turn, the LP. A spinal fluid analysis should always include glucose and protein measurement and a total and differential cell count. Depending on the clinical situation, other studies can be obtained, including microbial cultures (bacterial, fungal, viral, mycobacterial), special stains, and cytology.

CT or magnetic resonance imaging (MRI) can provide essential information in diagnosing and managing patients with increased ICP. Although MRI provides better anatomic differentiation than CT, it is often unavailable in the emergency setting; therefore, CT is performed more often than MRI. If a mass lesion is suspected, then neuroimaging (regardless of modality) should include contrast enhancement. Both modalities are effective in evaluating the cause of intracranial hypertension and are performed primarily to determine the presence of a mass lesion. The only exception is in the patient suspected of having a subarachnoid hemorrhage, when CT followed by LP remains the mainstay of initial diagnosis. It is important to note that children with severe traumatic brain injury (TBI) may not demonstrate radiologic signs on CT to indicate intracranial hypertension. Finally, ultrasonography is a reasonable alternative to CT or MRI in infants suspected of having aqueductal stenosis (Figure 364-2). Other neuroimaging studies, such as angiography, rarely play a role in the initial diagnostic management of intracranial hypertension.

**Figure 364-2** A coronal head ultrasound of a baby born at 30 weeks' gestation with a history of an intraventricular hemorrhage with increasing head circumference. Prominent dilated lateral ventricles (*white arrows*) and a clot-filled third ventricle (*black arrow*) are demonstrated.

## MANAGEMENT

Rapidly recognizing and stabilizing the patient suspected of having acutely increased ICP is essential in preventing greater morbidity and mortality. The goal of early management is to lower ICP without compromising cerebral perfusion and to identify the cause so that definitive therapy can be provided, whether medical or neurosurgical. Management is usually directed toward definitive therapy for patients with chronically elevated ICP.

As in any emergency, the first step in management is to assess the airway, breathing, and circulation (the ABCs). Also useful is to obtain a fingerstick glucose and, in the case of trauma, to expose the patient completely so as to identify injuries. The following initial steps should be taken when acute increased ICP is suspected:

1. Stabilize the airway. In most instances, this step requires rapid, controlled intubation, taking care to minimize any patient Valsalva maneuvers, which increase ICP further, albeit transiently.
2. Obtain intravenous (IV) access. Use only isotonic solutions, minimizing fluids initially unless circulatory compromise is evident.
3. Measure the vital signs and assess the neurologic state rapidly and frequently.
4. Position the head at 30 degrees and maintain a midline position in the event an injury to the cervical spine exists.
5. Maintain adequate intravascular volume and blood pressure.
6. Maintain adequate oxygenation.

Following these initial maneuvers, further interventions should be attempted based on the patient's clinical situation. The pediatric section of the Society of Critical Care Medicine and the World Federation of Pediatric Intensive and Critical Care Societies issued evidence-based practice guidelines for the acute medical management of severe TBI in infants, children, and adolescents that provide specific recommendations as they relate to acute intracranial hypertension.

treatment. These guidelines were adapted from previously published guidelines for adult TBI treatment. Based on these guidelines, further interventions to consider for treating intracranial hypertension are discussed in the following sections.

### Monitoring Intracranial Pressure and Removing Cerebrospinal Fluid

There is growing evidence for the benefit of monitoring ICP despite the lack of Level I evidence, especially in severe TBI. Maintaining normal ICP allows for the maintenance of adequate CPP, oxygenation, and metabolic substrate delivery while preventing cerebral herniation. ICP- and CPP-targeted protocols and therapies have improved outcomes. ICP monitoring and control of intracranial hypertension have become standards of care in adult patients with severe TBI treated at many hospitals with neurocritical care facilities and are recommended by the Brain Trauma Foundation. However, its implementation and use in the pediatric population is quite sporadic. The guidelines in the pediatric population support ICP monitoring and recommend treatment goals to keep ICP under 20 mm Hg and maintain CPP above 40 mm Hg.

Numerous invasive devices are available to assess ICP, including intraventricular catheters that allow CSF drainage, therefore reducing ICP. This is the most accurate and cost-effective method of monitoring ICP. The disadvantage is the higher risk of infection, seizures, and hemorrhage compared with other available devices. A fiberoptic catheter tip pressure transducer or strain gauge device placed within the brain parenchyma provides an effective way to continuously monitor ICP with minimal morbidity. Intraparenchymal catheters that measure brain tissue oxygenation ( $\text{PbO}_2$ ) and oxygen delivery ( $\text{DO}_2$ ) and microdialysis catheters that allow for measurement of substrates such as pyruvate and lactate enable monitoring for brain ischemia and can be used in conjunction with ICP monitoring. Jugular bulb indwelling catheters enable measurement of cerebral venous oxygenation. Transcutaneous, transcranial near-infrared spectroscopy can assess ICP and cerebral perfusion indirectly and noninvasively.

In severe TBI, standard ICP and CPP monitoring often do not reflect true  $\text{DO}_2$ . The combination of ICP and  $\text{PbO}_2$  monitoring using  $\text{PbO}_2$ -directed critical care is associated with improved outcomes. High ICP correlates with decreased cerebral  $\text{DO}_2$ . Monitoring ICP and  $\text{PbO}_2$  allows early recognition of low oxygen delivery states, hence enabling appropriate therapeutic intervention.

### Hyperventilation

Cerebral blood flow is exquisitely sensitive to carbon dioxide levels. Low carbon dioxide levels lead to cerebral vasoconstriction, whereas elevated levels lead to dilation. Early hyperventilation (HV) of the patient with increased ICP leads to a decrease in cerebral blood volume and a decrease in ICP. This method is the most rapid and effective way to lower ICP acutely. This effect is transient; therefore, other methods must be employed to maintain normal or near-normal ICP. Current recommendations support short periods of

hyperventilation ( $\text{PaCO}_2$  30–35 mm Hg) as therapeutically useful.

Further decreases can lead to a significant decrease in cerebral blood flow, producing ischemia and further increasing ICP. Failure to respond to HV is often a poor prognostic sign. Evidence suggests that the alkalizing effect of HV, and, therefore, lowered ICP, can be minimized through IV buffers, such as tris hydroxymethyl aminomethane.

HV, although long a mainstay in the treatment of increased ICP, was recently called into question as possibly causing more harm than good. HV induces a more pronounced change in cerebral blood flow than in cerebral blood volume, which can lead to a reduction in oxygen pressure despite the beneficial affect on CPP and ICP. One study found that aggressive HV had worse outcomes for patients with early, severe head trauma than those who were normocapnic. Although HV is the most rapid method for lowering ICP acutely, aggressive HV is not beneficial for the chronic treatment of increased ICP. The recent guidelines suggest considering aggressive HV ( $\text{PaCO}_2 < 30$  mm Hg) for refractory intracranial hypertension for brief periods while monitoring for brain ischemia, including brain tissue  $\text{O}_2$  ( $\text{PbO}_2$ ), cerebral blood flow, or jugular venous oxygen saturation. Mild HV ( $\text{PaCO}_2$  30–35 mm Hg) may be considered for longer periods for intracranial hypertension refractory to other modes of treatment.

### Osmotic Agents and Diuretics

Intravenous osmotic agents (mannitol and glycerol) do not permeate the blood–brain barrier and, therefore, draw fluid from the intracellular brain compartment to the vascular space, thereby reducing ICP and allowing increased cerebral perfusion. Traditionally, mannitol is favored over glycerol; however, one study found that although mannitol decreased ICP, it did not improve cerebral oxygen pressure. Mannitol is given rapidly in an initial IV bolus of 0.5 to 1 g/kg. Following this administration, additional boluses ranging from 0.25 to 0.5 g/kg should be given every 2 to 5 hours, depending on the patient's status. Response to IV mannitol is rapid and usually occurs within 10 to 20 minutes. Serum osmolarity should be maintained in the 295- to 320-mOsm/L range. Mannitol is excreted renally, so it cannot be given in the setting of renal failure because it can provoke potentially life-threatening pulmonary edema. Glycerol acts in a similar fashion to mannitol, but has lost favor because of its potential for creating a reversed osmotic gradient and a rebound increase in intracranial pressure, intravascular hemolysis, and other side effects.

Loop diuretics such as furosemide reduce ICP by provoking a diuresis of water and electrolytes, thereby establishing a gradient between the intravascular compartment and the brain. Diuretics must be used cautiously in patients with TBI and subarachnoid hemorrhage because volume depletion can worsen the outcome. Diuretics are often used in combination with osmotic diuretics, but are seldom used alone. Care must be taken when using any of the aforementioned agents to maintain intravascular volume and adequate blood pressure. Electrolytes must be monitored carefully.

### Hypertonic Saline

The use of hypertonic saline for treatment of increased ICP has become much more popular because of a number of small trials demonstrating its efficacy and safety. It is administered in various concentrations and volumes of 3% to 23.4% hypertonic saline via IV. IV boluses can reduce ICP and augment CPP for several hours. Hypertonic saline creates an osmotic gradient and draws water from the intracellular and extracellular spaces into the intravascular compartment. It can be given quickly and requires lower fluid volumes than osmotic agents. Central venous access is required for administration, although the first dose may be given peripherally in emergent situations. No immediate concern exists for volume depletion, as can occur with mannitol. The potential side effects include hyperosmolar central pontine myelinolysis, congestive heart failure, subdural hematomas, and, rarely, coagulopathy. The trauma guidelines provide recommendations for the continuous infusion of 3% saline between 0.1 and 1.0 mL/kg/hour administered on a sliding scale with the minimal dose needed to maintain ICP under 20 mm Hg. Alternatively, periodic infusions of 23.4% NaCl can be administered as 30-mL boluses over 15 to 30 minutes in the manner of mannitol for ICP spikes greater than 20 mm Hg and have been shown to be as effective and possibly safer than mannitol. Serum osmolarity should be maintained below 360 mOsm/L when using hypertonic saline as the only hyperosmolar therapy to control brain edema.

### Neuromuscular Blockade

Using agents such as pancuronium and vecuronium can effectively decrease ICP by preventing maneuvers that increase intrathoracic pressure, such as coughing, straining, or *bucking* the ventilator. The physician must remember that these agents do not provide analgesia or sedation; therefore they should be used in conjunction with analgesic agents and short-acting sedatives. Succinylcholine should be avoided for its potential for transiently raising intracranial pressure.

### Temperature Control

Hyperthermia leads to greater cerebral metabolism; therefore, measures should be taken to prevent body temperature elevation. This process generally includes judicious use of antipyretics, cooling blankets, and antibiotics if infection is suspected. Conversely, hypothermia decreases cerebral metabolism and may be advantageous in managing elevated ICP, as long as shivering is prevented and efforts are made to maintain full cardiorespiratory function. Although the guidelines provide Level II and Level III recommendations for the use of moderate hypothermia (32°C–33°C) in early severe TBI to reduce intracranial hypertension, a recent major trial of hypothermia in pediatric TBI was stopped because of futility. Body temperature should be maintained between 36°C and 37°C (96.8°F and 98.6°F).

### Seizure Control

Seizure activity, whether clinical or subclinical, places excessive metabolic demand on already compromised

brain tissue. Treatment with antiepileptic drugs is necessary for any patient who is having or is suspected of having seizures, especially if neuromuscular blocking agents are to be used. In general, diazepam (0.1 mg/kg/dose IV) or lorazepam (0.05–0.1 mg/kg/dose IV) is to be used in treating acute seizures. For more prolonged therapy, phenytoin, fosphenytoin (a water-soluble prodrug of phenytoin), or phenobarbital can be used. Phenytoin and fosphenytoin have the distinct advantage of not depressing mental status. Phenytoin needs to be given slowly (50 mg/min). Although fosphenytoin can be given more rapidly (150 mg/min), it is water soluble and, therefore, can also be given intramuscularly. Levetiracetam has gained considerable popularity for its favorable side-effect profile and has consequently become the preferred first-line agent in seizure prophylaxis in many centers. A recent phase II Levetiracetam trial for children with acute head injury at risk for post-traumatic epilepsy showed both safety and efficacy. If possible, the cause of seizure activity (eg, fever, drug toxicity, hypoglycemia, electrolyte abnormalities) should be identified and treated.

### Corticosteroids

Corticosteroids are not currently recommended in managing acutely elevated ICP associated with head trauma, intracerebral hemorrhage, and ischemic stroke per the guidelines for management of pediatric severe TBI. Several controlled studies involving the use of glucocorticoids in head injury did not find any change in outcome or benefit for controlling increased ICP. However, they do have clear utility in managing edema associated with brain tumors and refractory pseudotumor cerebri. Their mechanism of action is unknown, but hypotheses include stabilizing the blood-brain barrier, enhancing brain energy supplies, decreasing tumor growth, reducing CSF production, and stabilizing cellular membranes. Dexamethasone is generally used.

### Glycemic Control

Hyperglycemia after head injury is associated with a poorer outcome than that for patients who are normoglycemic. Many centers now remove glucose from IV fluids and aggressively treat hyperglycemia. However, there is also evidence that intensive insulin therapy significantly increases the risk of hypoglycemia that may also adversely affect neurologic outcomes. Hence, it is suggested that intermediate glycemic goals may be the most appropriate approach.

### High-Dose Barbiturates

Treating refractory increased ICP with high doses of barbiturates can sometimes be effective. These agents act to decrease cerebral blood flow and metabolism. Pentobarbital is given for prolonged therapy; in general, an IV loading dose of 3 to 10 mg/kg is given followed by a maintenance infusion of 1 to 2 mg/kg/hour. The dose should be titrated based on the electroencephalogram with a goal of obtaining a burst-suppression pattern. This therapy should be maintained for 24 hours or more and then tapered. Side effects are common and include myocardial suppression and hypotension, often requiring pressors. Which groups of refractory increased ICP patients benefit from this therapy has

not yet been determined. Etomidate has also been demonstrated to effectively reduce ICP in severe TBI while increasing CPP. However, it is also associated with adrenal suppression. Pentobarbital should be used only when all other medical and surgical therapies have failed.

### Surgical Decompression

Obviously, removing large intracranial masses causing acutely increased ICP can be lifesaving. Surgery may also play a role in decreasing ICP in select patients with large intracerebral hemorrhages by removing the clot, in trauma patients with massive edema and contusion, or in patients who have a large cerebral infarction through craniectomy or decompression of the edematous mass. In the latter 2 instances, surgery is performed after all other measures have failed and increased ICP becomes refractory, but it should be considered before the ICP critically impairs the CPP.

The trauma guidelines recommend considering decompressive craniectomy to treat severe TBI and medically refractory intracranial hypertension, particularly when a potentially recoverable brain injury occurs. Although mortality in children with severe TBI remains high, craniotomy has been shown to be effective in reducing ICP and can be associated with favorable outcomes in surviving patients.

In pseudotumor cerebri, management is based on symptoms (intractable headache) or when signs of papilledema or visual loss are detected. Imaging studies are recommended to screen for mass lesions or hydrocephalus, although most have normal scans. CT of the head may show small, slit ventricles. MRI of the brain with gadolinium enhancement is the preferred modality for its sensitivity in screening for other conditions. Magnetic resonance venography is recommended for patients with suspected dural venous sinus thrombosis and may show extraluminal narrowing of the transverse sinus that may be a typical feature of pseudotumor cerebri. LP is recommended to document opening CSF pressure and may be used therapeutically to decrease ICP by draining CSF. Medical management includes the use of carbonic anhydrase inhibitors (acetazolamide) to decrease CSF production. Digoxin has also been suggested as a comparable alternative with the same effect, but lesser side effects. Patients with severe symptoms or visual loss, or failing standard medical therapy, may also benefit from a short course of high-dose corticosteroids (prednisone).

Patients with pseudotumor cerebri failing medical therapy or those experiencing progressive visual loss may be considered for surgical treatment that includes CSF shunting procedures (ventriculoperitoneal, ventriculoatrial, or lumboperitoneal shunt) or optic nerve sheath fenestration.

### Future Trends

In the future, cerebral protectants, such as free radical scavengers, excitotoxic amino acid antagonists, laze-roids, and *N*-methyl-D-aspartate receptor antagonists, may be part of the cocktail in the initial emergent management of acutely increased ICP.

## OUTCOME

Increased ICP is a major complication that affects morbidity and, possibly, ultimate outcome in at least 50% of children who have severe head injuries and in children who are comatose from other cerebral insults (eg, hypoxia, infections, metabolic disorders). It is still uncertain which variables—ICP, CPP, or initial Glasgow coma scale score (see Table 360-2 in Chapter 360, Head Injuries)—are helpful in predicting prognosis. Emerging studies are exploring various biomarkers in CSF and blood that may predict outcomes in brain injury. Regardless, significant morbidity remains for children with increased ICP. Clearly, in select children with mass lesions or treatable metabolic disorders, early identification and treatment before a catastrophic increase in ICP occurs will improve outcome. Evidence has shown marked reduction in mortality and decreased rate of intracranial hypertension when the guidelines for management of severe TBI are adhered to.

With respect to neurologically stable patients who exhibit evidence of chronically increased ICP, management is directed toward definitive therapy; that is, evacuating the chronic subdural hematoma, appropriate tumor management (corticosteroids, surgery or radiation plus chemotherapy or both), and treatment with acetazolamide, loop diuretics, steroids, or a lumbar drain in patients who have more benign causes of intracranial hypertension.

### WHEN TO REFER

- Macrocephaly or accelerating head growth (*crossing percentiles*)
- Chronic unremitting headache or new onset of severe headache
- Mild papilledema
- Visual abnormalities (field cuts, diplopia)
- Developmental arrest or regression

### WHEN TO ADMIT

- Bulging fontanel
- Altered mental status
- Prolonged seizures
- New focal neurologic deficits
- Moderate to severe papilledema
- Cushing triad (widened pulse pressure; bradycardia; and deep, slow respirations)

## Chapter 365

# ACUTE KIDNEY INJURY

Stuart L. Goldstein, MD; Horacio Esteban Adroque, MD

## DEFINITION OF TERMS

Acute kidney injury (AKI) is a syndrome of sudden diminution or cessation of kidney function. The term AKI has been adopted to replace the previous clinical nomenclature of acute renal failure (ARF), because it focuses attention on early recognition of kidney insult and interventions to prevent or mitigate the effects of significant renal failure. Until 2004, more than 30 AKI/ARF definitions existed in the published literature. However, in the past 10 years, standardized, multi-dimensional, graded AKI diagnostic criteria have been developed and validated to demonstrate increasing morbidity and mortality in patients with increasing AKI severity. These criteria include the RIFLE criteria (risk, injury, failure, loss and end-stage kidney disease), the Acute Kidney Injury Network (AKIN) criteria, and the pediatric modified RIFLE (pRIFLE) criteria. Each classification system uses increasing relative changes in serum creatinine ( $S_{Cr}$ ) concentration and increasing duration of oliguria in its definition. In 2012, the Kidney Disease Improving Global Outcomes (KDIGO) AKI consensus work group harmonized the above criteria (see Table 365-1). The KDIGO criteria should be considered the standard

AKI diagnostic system, because each of its components has been validated in both pediatric and adult patient populations. It is important to understand that AKI will be fulfilled by the criteria, in most instances prior to the classic metabolic derangements previously associated with ARF, including hyperkalemia, acidosis, uremia, and fluid overload. Nonetheless, clinical decision making is still often guided by the relative volume of urine produced by a patient with AKI.

- **Nonoliguric state:** Sufficient urine volume to allow for administration of necessary fluids, nutrition, blood products, and medication without resulting volume overload
- **Oligoanuric state:** Insufficient urine volume to allow for administration of necessary fluids, nutrition, blood products, and medication without resulting volume overload

## EPIDEMIOLOGIC FEATURES

The causes of AKI in children have changed from primary kidney diseases to secondary effects of other systemic illnesses or their treatment. In studies of acutely ill hospitalized patients, the most common causes of AKI in children are congenital heart disease, sepsis, and nephrotoxic medicines.

The 3- to 5-year patient survival of an AKI episode is 57%; approximately 60% of patients demonstrate evidence of chronic kidney injury. Routine evaluation of all pediatric AKI survivors for evidence of chronic kidney disease, hypertension, and microalbuminuria may help prevent the long-term sequelae of AKI.

## ETIOLOGY

The classification of AKI should focus on determining the cause and site of kidney insult (Table 365-2). Factors leading to diminished kidney function are often grouped according to pre-renal, renal (parenchymal), postrenal, or a combination of these mechanisms. However, the recent discovery and validation of novel urinary AKI biomarkers, which provide information regarding the mechanism for particular causes of AKI, have led to a

**Table 365-1** Kidney Disease Improving Global Outcomes Acute Kidney Injury Staging Criteria

KDIGO STAGE	SERUM CREATININE	URINE OUTPUT
1	1.5–1.9 times baseline OR ≥0.3 mg/dL increase	<0.5 mL/kg/hr for 6–12 hr
2	2.0–2.9 times baseline	<0.5 mL/kg/hr for ≥12 hr

movement away from these previous groupings to the concept and terms of functional and structural AKI.

Functional (prerenal) causes are those that diminish kidney perfusion without producing actual parenchymal injury. In children, hypovolemia is the most common clinical situation in which diminished kidney function occurs, and it usually results from dehydration associated with acute gastrointestinal losses. Hypovolemia may also occur in shock as the result of hemorrhage, burns, sepsis, or trauma. Less-common causes of functional AKI are those that diminish renal blood flow in the absence of hypovolemia, such as congestive heart failure, kidney vascular obstruction from thrombosis or embolism, nephrotic syndrome, liver failure, or increased kidney vascular resistance occasionally after anesthesia or surgery. Although  $S_{Cr}$  increase and oliguria can both occur in functional AKI, normal compensatory kidney tubular function usually persists, characterized by high urinary osmolality and low urinary sodium concentrations as the result of kidney water and sodium conservation.

AKI from intrinsic structural injury may result from glomerular, tubular, or interstitial disorders. AKI from glomerular injury results most commonly from any of the glomerulonephritides or the microangiopathy of the hemolytic-uremic syndrome. Tubular injury is often the result of prolonged ischemia or exposure to a variety of nephrotoxins. Renal ischemia may be seen in hypotensive episodes, severe dehydration, sudden hemorrhage, or sepsis. Tubular toxins may be endogenous (eg, hemoglobin, myoglobin) or exogenous (eg, medications such as aminoglycoside antibiotics), and various chemicals (eg, carbon tetrachloride, diethylene glycol, heavy metals) may cause acute parenchymal kidney failure. Drugs can also produce acute kidney failure by

inducing a hypersensitivity reaction (drug-induced interstitial nephritis). Diffuse pyelonephritis also may result in AKI, particularly in infants. Kidney cortical necrosis associated with infection, hemorrhage, or dehydration can produce significant irreversible injury to both glomeruli and tubules.

Post-renal AKI results from obstruction to the urinary flow, either from internal causes (eg, stones, anatomical obstruction from urethral or ureteral stenosis) or external compression (eg, masses, abdominal compartment syndrome).

## EVALUATION

### Relevant History

The processes contributing to kidney functional impairment can often be identified from the patient's history. Reduction in urine production is not necessary for fulfillment of the AKI definition, because kidney failure occurs not only in anuric states, but also in patients with oliguric or nonoliguric states. Some kidney insults, such as various glomerulonephritides and hemolytic-uremic syndrome, are often associated with oligoanuric AKI; others, such as aminoglycoside toxicity, will more often cause nonoliguric kidney failure. Determining the type of insult provides the physician with insights into the possible manifestations of kidney failure, the probable duration of AKI, and the overall prognosis. The history often helps distinguish between an episode of AKI in an otherwise healthy child and the acute deterioration of kidney function in a child who has preexisting, undiagnosed, chronic kidney disease. History of urinary abnormalities, fatigue, pallor, slowed linear growth, poor school performance, and anorexia extending over a period would lead the physician to suspect the latter.

**Table 365-2**

**Clinical Tests to Differentiate Functional From Structural Oliguric Acute Kidney Injury**

TEST	FUNCTIONAL AKI	STRUCTURAL AKI	DISCRIMINATION
<b>SODIUM CONSERVATION</b>			
Urine sodium concentration ( $U_{Na}$ )	<20 mEq/L	>40 mEq/L	Poor
Fractional excretion of sodium ( $FE_{Na}$ ); $FE_{Na} = (U_{Na} \times S_{Cr}) / (S_{Na} \times U_{Cr}) \times 100$	<1	>1	Good
Fractional excretion of urea ( $FE_{urea} = (U_{UN} \times S_{Cr}) / (BUN \times U_{Cr}) \times 100$ )	<35	$\geq 35$	Good for patients on diuretics
<b>WATER CONSERVATION</b>			
Urine osmolality ( $U_{osm}$ )	>500 mOsm/L	<350 mOsm/L	Poor
Urine-serum osmolality ratio ( $U_{osm}/S_{osm}$ )	>2	<1.1	Fair
Response to diagnostic challenge with intravenous mannitol and furosemide	Urine flow increase	No change	Good

AKI, acute kidney injury; BUN, blood urea nitrogen; Cr, creatinine; Na, sodium; S, serum; U, Urine; UN, urea nitrogen.

Children with nonoliguric acute tubular necrosis can have fractional excretion of sodium less than 1%. The  $FE_{Na}$  test is only helpful for oliguric AKI in patients not receiving loop diuretics. The threshold for  $FE_{Na}$  in neonates is 3% and not 1%.

Acute kidney injury may be heralded by seizures. Seizures can be precipitated by hypocalcemia, hypertensive encephalopathy, uremia, and water intoxication. It is not unusual for a child to first have a sudden onset of seizures and other signs of central nervous system dysfunction, only to be found to have AKI.

### Physical Findings

Many children with AKI will have markedly diminished urine output. Complete anuria is unusual and leads to consideration of a catastrophic renovascular event or urinary obstruction. In the child who has anuria or oliguria, fluid retention can produce edema, water intoxication, vascular overload with congestive heart failure, pulmonary edema, hypertension, or any combination of these. In many instances, the fluid overload is iatrogenic, resulting from attempts to increase urinary output by increasing fluid intake. Early detection of fluid retention is determined best by short-term weight gain on serial measurements and carefully recorded intakes and outputs, with appropriate allowances for insensible fluid losses. In contrast, nonoliguric AKI may be clinically covert; it is usually suspected only after laboratory tests reveal an elevation in  $S_{Cr}$  or an electrolyte imbalance.

In the intensive care unit (ICU), where daily weight assessment is often not feasible, relative percent fluid overload (%FO) can be calculated with the following formula:

$$\%FO = [(Fluid\ intake\ (liters) - Fluid\ output\ (liters))/ICU\ admit\ weight\ (kg)] \times 100\%$$

Relative %FO has been shown in multiple pediatric ICU studies to be independently associated with

mortality and prolonged ventilator support. It is important to note that measured intake and output were used for these studies and insensible losses were considered to be negligible.

### Laboratory Findings

The biochemical disturbances that contribute to clinical findings in AKI are complex and interrelated. Inherent to the diagnosis of severe AKI is the accumulation of nitrogenous waste products, characterized by a rise in blood urea nitrogen and  $S_{Cr}$ . If hypotonic fluids have been used in excess to hydrate the patient, then dilutional hyponatremia and anemia may affect central nervous system and cardiac function adversely.

Hyperkalemia is often the result of injudicious potassium administration or inadequate renal potassium excretion. (Table 365-3 lists treatment options.) Hyperkalemia is a potentially life-threatening complication of AKI and can be especially severe in disease states associated with cellular damage and the consequent release of intracellular potassium (hemolysis, burns, trauma, and infections). Hyperkalemia produces a state of increased neuromuscular excitability, including a vulnerability to cardiac arrhythmias. Unfortunately, hyperkalemia produces no consistent physical signs; diagnosis depends on the measurement of serum potassium and, if indicated, assessment of the electrocardiogram for evidence of altered cardiac electrical activity.

In AKI, metabolic acidosis develops as the result of the kidney's failure to excrete hydrogen ions and reabsorb bicarbonate. Furthermore, any state associated with increased catabolism, such as shock, fever, poor caloric intake, or extensive tissue damage, may

**Table 365-3** Treatment of Hyperkalemia in Pediatric Patients

AGENT	DOSE	EFFECT	REMARKS
Calcium gluconate (10%)	50 mg/kg IV over 2–4 min	Rapid but transient	Monitor electrocardiogram for bradycardia during injection; may be repeated but <i>not likely</i> to be effective.
Sodium bicarbonate (8.4%) Glucose (50%)	1–2 mEq/kg IV by slow push 0.5–1 g/kg IV by slow push	Rapid but transient Within 1–2 hr	Repetition <i>not</i> recommended. Attempt to increase blood glucose to 250 mg/dL; may be maintained by infusion of 30% glucose at rate equal to insensible fluid loss.
Insulin (regular)	0.1 units/kg IV	Rapid	Give <i>only</i> with hypertonic glucose infusion (30%).
Sodium polystyrene sulfonate (Kayexalate)	1 g/kg PO or PR	3–6 hr	Side effects: gastric irritation (nausea and vomiting), diarrhea, or fecal impaction; PO more effective than PR; enemas should be retained >60 min—removed by cleansing enema; may cause <i>hypokalemia</i> : use cautiously in patients who tolerate sodium loads poorly; also chelates $Ca^{+}$ and $Mg^{+}$ . The FDA has placed a warning for the medication with respect to the potential for intestinal necrosis. <sup>a</sup>

$Ca^{+}$ , Calcium ion; IV, intravenous;  $Mg^{+}$ , magnesium ion; PO, orally; PR, rectally.

<sup>a</sup>Full warning available at [www.fda.gov/Safety/MedWatch/SafetyInformation/ucm186845.htm](http://www.fda.gov/Safety/MedWatch/SafetyInformation/ucm186845.htm).

accentuate the degree of acidosis as a result of increased production of organic and inorganic acid radicals. The acidosis promotes further hyperkalemia resulting from movement of intracellular potassium into the extracellular space as the body attempts to accommodate the higher hydrogen ion concentration. Respiratory compensation for an underlying metabolic acidosis may cause low carbon dioxide pressure, resulting from tachypnea or Kussmaul breathing.

Failure of phosphate excretion can lead to hyperphosphatemia. The hypocalcemia associated with hyperphosphatemia may exhibit clinically as tremors, tetany, or seizures.

## MANAGEMENT

Acute kidney injury management should begin before consulting with a nephrologist and before initiating renal replacement therapy. Maintenance of adequate urine volumes and prevention and treatment of metabolic derangements comprise the goals of therapy in children with AKI. Preservation or restoration of renal perfusion with appropriate fluid resuscitation and inotropic agents is essential and is the first measure to maintain urine output in critically ill patients.

*Goal-directed fluid therapy* is a term that represents the use of physiologic endpoints such as heart rate, central venous pressure, and mean arterial pressure to guide initiation and termination of fluid resuscitation of patients in shock. Goal-directed fluid therapy leads to better survival in adults with shock. Adult patients who receive early goal-directed fluid therapy in the emergency department (ED) receive more fluid in the ED, but receive less fluid and have better survival in the ICU compared with patients who receive standard therapy. Although fluid resuscitation in critically ill children is essential to treat acute hypovolemic and septic shock state, the concept that worsening fluid overload is associated with worse outcomes in critically ill pediatric patients who require renal replacement therapy has been the focus of recent pediatric study. Both single-center data and a multicenter effort, the Prospective Pediatric Continuous Renal Replacement Therapy Registry Group (known as the ppCRRT Registry) demonstrate that worsening fluid overload in patients receiving continuous renal replacement therapy (CRRT) is an independent risk factor for mortality, as assessed by the pediatric risk of mortality score, irrespective of the severity of illness. These data, coupled with the predilection for early multiorgan system failure and death in critically ill children, argue for early and aggressive initiation of renal replacement therapy. Earlier initiation at lesser fluid overload degrees may allow for more expeditious optimal nutrition and blood product provision without further fluid or waste product accumulation, and may prevent the worsening volume overload and, in particular, pulmonary edema. Because most pediatric drug dosing is based on ICU admission weight, worsening fluid overload might increase the volume of distribution of inotropes, antimicrobials, and chemotherapeutic agents, thereby resulting in underdosing.

Medication dosing should be altered for specific drugs that are primarily eliminated by the kidneys; drug

dose or interval (or both) may need to be altered based on the level of kidney dysfunction. In addition, drug concentrations can be wholly or partially reduced by dialysis in patients who receive either intermittent or continuous renal replacement therapy. Factors associated with enhanced dialytic elimination include low volume of distribution and low protein binding.

Well-designed prospective randomized studies of adult patients at risk for acute tubular necrosis have called into question the utility of intravenous furosemide or renal-dose dopamine in preventing oliguria. Other recent studies support the use of fenoldopam, a dopamine  $\alpha$ 1-agonist, to prevent AKI in certain critically ill adult populations. To date, no large prospective, controlled study has been conducted with respect to the optimal pharmacologic management of pediatric AKI.

### WHEN TO REFER

- For guidance on diagnostic evaluation
- Management of complex fluid, mineral, electrolyte, and blood pressure abnormalities
- Evaluation of dialysis options and preparation for and implementation of dialysis or CRRT treatment
- Disease-specific management

### WHEN TO ADMIT

- When AKI is unexplained, rapidly progressive, or oliguric or anuric
- In the presence of severe or potentially dangerous fluid or metabolic abnormalities (eg, hyperkalemia, hypocalcemia, acidosis, clinical fluid overload, dehydration)
- For renal biopsy

## Chapter 366

## MENINGOCOCCEMIA

Mary T. Caserta, MD

## DEFINITION OF TERMS

Meningococcemia is a classic example of fulminant bacterial sepsis and is the most dreaded consequence of infection with *Neisseria meningitidis*. Although occult or chronic meningococcemia is detected occasionally, patients with the severe form of the disease can progress from a state of good health to death in hours, regardless of whether meningitis is present.

## EPIDEMIOLOGY AND ETIOLOGY

*Neisseria meningitidis* is an aerobic gram-negative coccus that appears typically in pairs (diplococci) with the adjacent sides flattened. The organism is enclosed by a cell envelope containing outer membrane proteins and lipopolysaccharide (endotoxin) and by a polysaccharide capsule. Thirteen serogroups have been identified based on the antigenic structure of the capsular polysaccharide. Six of these serogroups are responsible for most human disease: serogroups A, B, C, Y, W-135, and X. Additionally, multilocus sequence typing (MLST), a procedure for sequencing housekeeping genes of *N meningitidis*, has led to the recognition of sequence types (STs) used in epidemiologic investigations.

*N meningitidis* is found only in the human nasopharynx and is spread via respiratory droplets or contact with secretions. Invasive meningococcal disease is an uncommon event, with most individuals colonized only intermittently with the organism. In nonepidemic conditions, about 5% to 30% of the population is colonized, with the peak age of colonization in adolescence. Closed populations, such as military recruits, can have rates as high as 80%, and carriage rates are even higher in household contacts of infected patients. Colonization with both pathogenic and nonpathogenic *Neisseria* spp., in addition to other gram-negative organisms that have structurally similar carbohydrate antigens, induces the development of natural immunity to *N meningitidis*.

Nonetheless, *N meningitidis* causes both epidemic and endemic disease worldwide, with fluctuations in the incidence of disease usually varying over 5- to 8-year cycles. Despite these fluctuations, *N meningitidis* remains a leading cause of meningitis and sepsis in children and young adults. Between 1998 and 2007, 1525 cases of meningococcal disease occurred annually in the United States, with an overall incidence of 0.53 cases per 100,000 people. The highest incidence of disease is consistently found in infants, with an attack rate of 5.38 cases per 100,000 population. From 20% to 25% of all cases of meningococcal disease occur in children younger than 2 years, when passively acquired maternal antibody concentrations have reached their nadir and a substantial number of children have not yet acquired

protective antibodies after colonization. A second, smaller peak of disease is found in adolescents and young adults 14 to 24 years of age, with rates of 0.78 cases per 100,000 population.

Risk factors associated with the development of invasive disease in adolescence include male gender, symptoms of an upper respiratory tract infection, marijuana use, and attendance at night clubs. Polymorphisms in genes involved in host response also appear to confer an increased susceptibility to disease with *N meningitidis*. These genes include factor H, a complement regulator, interleukin-1 receptor antagonist (IL-1RA), surfactant protein A, and carcinoembryonic antigen cell adhesion molecules. Pathogen factors that have been associated with virulence include the polysaccharide capsule, the repertoire of adhesin molecules used by the organism, and the regulation of bacterial metabolism, with invasive disease linked to only a subset of highly virulent strains.

The serogroup distribution of *N meningitidis* causing invasive disease varies across regions. From 1998 to 2007, serogroups B and C were each identified in about 30% of cases of meningococcal disease in the United States, with serogroup Y accounting for 35% of isolates. Despite the relative equality in the overall number of cases caused by each of these 3 serogroups, 52% of disease caused by serogroup C occurred in persons between 2 and 24 years of age, whereas almost half of disease caused by group B occurred in children younger than 9 years of age, making serogroup B meningococci more of a threat to the younger age groups. Serogroup Y disease has been found to be associated with older age groups and the clinical syndrome of pneumonia. The occurrence of meningococcal infection also varies with the seasons. Winter and spring constitute the peak time of disease in the United States. Several older studies have shown an association between meningococcal disease and influenza and other viral respiratory infections, although the exact nature of this interaction is not clear.

Fifty percent of cases of invasive meningococcal disease are associated with meningitis; about 35% are classified as bacteremia, 9% pneumonia, and 2% arthritis. The overall mortality rate for meningococcal disease is 5% to 15%. Patients with meningitis tend to have lower case fatality rates than those with bacteremia or pneumonia. Subgroups of patients, such as those who have fulminant meningococcemia, can have fatality rates as high as 50% to 80% despite aggressive therapy.

## CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

The classic signs of invasive meningococcal disease are hemorrhagic rash, meningism, and impaired consciousness (Figure 366-1). Fever and rash are consistent findings noted in about 70% of patients. Unfortunately, fever and rash are not specific to meningococcemia and have been described in many other infectious and noninfectious diseases (Box 366-1). In a study of more than 200 children in an emergency department with a non-blanching rash, 11% were found to have meningococcal disease. Children with meningococcemia were more likely to be judged ill by the investigators and to have a

body temperature of 38.5°C or higher, a purpuric rash, and a capillary refill time of more than 2 seconds. A similar study found that 15% of children with fever and hemorrhagic rash had documented invasive meningococcal disease. After a full evaluation, 45% of the children did not have a specific diagnosis identified, and presumably most had self-limited viral illnesses. Poor general condition, the presence of nuchal rigidity, more than 2-mm maximal diameter of skin hemorrhages, and a generalized distribution of the rash were highly associated with a diagnosis of invasive meningococcal disease. These 2 studies also confirmed the absence of meningococcal disease in children with petechial

**Figure 366-1** A 4-year-old white girl with acute meningococemia without meningitis. Note the nearly uniform distribution of petechiae over the trunk and extremities.

rashes confined to the area of distribution of the superior vena cava (above the nipple line).

Not only are fever and rash not specific for meningococcal disease, but in fact, the rash may be a late finding in the evolution of the clinical syndrome. Other common symptoms and signs include irritability or lethargy in slightly more than 50% of patients, vomiting in about 35% of children, and shock in 42%. Less frequent symptoms include delirium, headache, coryza, diarrhea, myalgia, and hypothermia. Because of the nonspecific nature of many of these symptoms, early recognition of a child with meningococcal disease is challenging, and physicians must maintain a high index of suspicion. The median time between onset of symptoms and hospitalization for pediatric patients is between 13 and 22 hours. The first specific signs noted by caretakers include abnormal color (pallor or mottling), leg pain, and cold hands and feet. These symptoms develop within the first 12 hours of illness and are present in more than one-third of the cases; hemorrhagic rash, neck stiffness, and confusion may develop in the second 12 hours of illness.

Once a rash has developed, the type and duration provide important information about the course and prognosis of the disease. Early in the infection, a tender, pink, maculopapular rash similar to that seen in rubella, secondary syphilis, or disseminated gonorrhea can appear on any part of the skin. The rash often fades rapidly with treatment, and patients who have this type of manifestation are less likely to have a fulminant course. A generalized petechial rash, most prominent on the distal extremities, including the palms and soles,

### BOX 366-1 Causal Agents and Illnesses in Which Petechiae or Purpura Occurs

Viruses	<i>Neisseria gonorrhoeae</i>
Varicella-zoster virus	<i>Neisseria meningitides</i>
Cytomegalovirus (congenital infection)	<i>Moraxella catarrhalis</i>
Variolavirus	<i>Haemophilus influenzae</i>
Coxsackieviruses	<i>Streptobacillus moniliformis</i> (rat-bite fever)
Echoviruses	<i>Pseudomonas aeruginosa</i> (erythema gangrenosa)
Colorado tick fever virus	<i>Yersinia pestis</i> (plague)
Rubella virus	<i>Bartonella henselae</i> (cat-scratch disease)
Measles virus	<i>Treponema pallidum</i> (congenital syphilis)
Alpha viruses (ie, Ross River fever)	<i>Borrelia species</i> (relapsing fever)
Lassa virus	<i>Trichinella spiralis</i> (trichinosis)
Marburg viruses	<i>Toxoplasma gondii</i> (congenital toxoplasmosis)
Nonviral Agents	Miscellaneous
<i>Rickettsia typhi</i> (murine typhus)	Henoch-Schönlein purpura
<i>Rickettsia prowazekii</i> (epidemic typhus)	Immune thrombocytopenic purpura
<i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever)	Kawasaki disease
<i>Ehrlichia canis</i>	Serum sickness
<i>Mycoplasma pneumoniae</i>	Poisons
<i>Streptococcus pyogenes</i> (scarlet fever)	Erythema multiforme
<i>Streptococcus pneumoniae</i>	Erythema nodosum
Enterococcal and viridans group streptococci (endocarditis)	Systemic lupus erythematosus

Modified and reprinted from Cherry JD. Cutaneous manifestations of systemic infections. In: Feigin RD, Cherry JD, eds. *Textbook of Pediatric Infectious Diseases*. 6th ed. Philadelphia, PA: WB Saunders; 2009:755–780, with permission from Elsevier.

usually is associated with meningococcal disease (Figure 366-2). Initially, the lesions are discrete, 1 to 2 mm in diameter, and found in clusters where clothing puts pressure on the skin. This rash must be differentiated from that seen with Rocky Mountain spotted fever, rat-bite fever, bacterial endocarditis, and *Enterovirus* spp. infections. Scrapings of petechial lesions reveal the organism about 70% of the time.

The most ominous manifestation of meningococcal disease is an ecchymotic or purpuric rash, with a centrifugal distribution usually present in cases of fulminant meningococcemia (Figure 366-3). Meningococcemia is the most common infectious cause of purpura. Patients with purpura fulminans have a 20% to 50% mortality rate. The case fatality rate also is significantly higher in patients who have petechiae for 12 hours or less. Therefore, a febrile child who has purpura or petechiae that have been present for fewer than 12 hours should be managed as a medical emergency. The differential diagnosis of illness with petechial or purpuric exanthems includes Rocky Mountain spotted fever, plague, measles, septicemia with other bacteria, and Henoch-Schönlein purpura (see Box 366-1 for a full list).

## EVALUATION

### History

The early recognition of meningococcemia is an important determinant of survival. Most children with

invasive meningococcal disease have an illness with symptoms and signs lasting only a few hours to a day. About 25% may report a recent respiratory illness, but in general, the children have no significant medical history. Patients often describe the acute onset of fever, nausea, vomiting, irritability or lethargy, and rash. Other symptoms include myalgia, leg pain, cold hands and feet, neck pain or stiffness, sore throat, diarrhea, headache, and abnormal skin color (Table 366-1).

### Physical Examination

The physical examination of a child or adolescent with suspected meningococcemia should be performed expeditiously and with close attention to the vital signs and skin findings. A maculopapular rash may precede the more classic generalized petechiae. Petechiae are often clustered, 1 to 2 mm in size, and more prominent on the distal extremities, including the palms and soles. Purpura may also be present with the petechiae. In addition to the skin findings, the adequacy of respiration, the central and peripheral circulation, and mental status need to be evaluated to determine the presence of shock. Because of the rapid evolution of meningococcemia, frequent reassessments are warranted.

### Laboratory Testing

An infant or child with signs and symptoms of invasive meningococcal disease should be evaluated immediately with aggressive monitoring and treatment as soon as the diagnosis is reasonably thought to be present; the use of early antibiotics is associated with a decreased risk for death in some studies. If the patient is being transported to a pediatric intensive care unit, blood should be drawn, antibiotics given, and intravascular access secured beforehand. The patient should be attended during transport by a physician prepared to treat shock and respiratory failure because the disease may worsen when endotoxin is liberated after antibiotic therapy. Initial laboratory tests should include a blood culture or polymerase chain reaction (PCR) test to identify the organism, a

**Figure 366-2** Meningococcemia showing striking involvement of the extremities with relative sparing of the skin of the child's body surface.

**Figure 366-3** Ecchymotic or purpuric rash is the most significant manifestation of meningococcal disease. Note the centrifugal distribution in this child with fulminant meningococcemia.

**Table 366-1****Cumulative Proportion of Children Developing Clinical Features During the Course of Meningococcal Disease**

	<b>FATAL CASES (n=103)</b>	<b>NONFATAL CASES (n=345)</b>	<b>OVERALL (95% CONFIDENCE INTERVAL [CI])</b>	<b>MEDIAN HOUR OF ONSET</b>
<b>EARLY SYMPTOMS</b>

complete blood count and differential, a partial thromboplastin time, a prothrombin time, measurement of fibrin breakdown products, and serum chemistries. If the patient is stable when first evaluated, a lumbar puncture should be performed to examine the cerebral spinal fluid for organisms, obtain cultures, and assess the prognosis more accurately. If the patient is not stable on initial assessment, the lumbar puncture should be deferred until a later time. Antibiotic therapy should never be withheld while waiting to obtain cerebrospinal fluid.

### Management

The recommended antibiotic regimen for treatment of meningococemia is aqueous penicillin G 250,000 to 300,000 units/kg of body weight per day in 4 to 6 divided doses (maximum of 12 million U/day). Although a small percentage of meningococcal isolates with intermediate susceptibility to penicillin have been identified in North America, no resistance to penicillin or ceftriaxone has been reported. Ceftriaxone, cefotaxime, and chloramphenicol are alternative antibiotics recommended for patients who have a serious allergy to penicillin (anaphylaxis). Antibiotic therapy generally is continued for 5 afebrile days or 7 days total. Rifampin is prescribed at the end of the course of penicillin to eliminate carriage of the organism from the nasopharynx (see below). Rifampin is not necessary if the patient has been treated with a third-generation cephalosporin because these agents are effective in eliminating carriage.

In addition to antibiotic therapy, patients with meningococemia often require aggressive supportive therapy in an intensive care setting, with invasive

monitoring of hemodynamic, neurologic, and respiratory function. Mechanical ventilation often is necessary to treat respiratory failure. Maintenance of optimal plasma expansion with intravenous fluids is the first step in stabilizing the circulatory system. Large amounts of fluid may be needed because of the capillary leak associated with endotoxic shock. Additionally, transfusions with platelets and fresh-frozen plasma may be necessary to correct the coagulopathy associated with meningococemia. Myocardial dysfunction precedes shock in meningococcal sepsis; therefore, the use of inotropic agents is recommended.

Supportive measures for severe purpura include treatments aimed at relieving the ischemic complications associated with vasculitis. Continuous epidural anesthesia may help in improving perfusion of the lower extremities and preventing gangrenous necrosis. The mechanism of action is thought to be vasodilation of partially occluded vessels through sympathetic blockade. If no evidence of coagulopathy exists, then an anesthesiologist can perform this type of regional block with an indwelling catheter in the caudal space. The topical administration of nitroglycerin can be useful in restoring blood flow to limited areas of skin and superficial tissues without notable adverse effects.

Other ancillary treatments include plasmapheresis, whole blood exchange, extracorporeal membrane oxygenation, and continuous venovenous hemodiafiltration. The bacterial load in whole blood measured by PCR is significantly associated with mortality, the need for dialysis or skin grafting, and limb or digit loss in meningococcal disease. The bacterial load is correlated with levels of endotoxin, and several studies have shown a link between plasma levels of endotoxin

**Table 366-2** Glasgow Meningococcal Septicemia Prognostic Score

POINTS	SCORE
Blood pressure <75 mm Hg systolic, age <4 yr and <85 mm Hg systolic, age >4 yr	3
Skin to rectal temperature difference >3°C	3
Modified Glasgow Coma Scale score <8 or deterioration of at least 3 points in 1 hr	3
Clinical deterioration in hour before scoring	2
Absence of meningitis	2
Extending purpuric rash or widespread ecchymoses	1
Base deficit (capillary or arterial) >8.0	1
Maximal score	15

A score of at least 9 has a sensitivity of 100%, a specificity of 95%, a positive predictive value of 73.7%, and a negative predictive value of 100% in predicting mortality.

Modified from Sinclair JF, Skeoch CH, Hallworth D. Prognosis of meningococcal septicaemia. *Lancet*. 1987;2(8549):38, with permission from Elsevier.

or tumor necrosis factor and multiorgan failure or disease severity, making the previously listed strategies theoretically attractive. The use of high-dose steroids in children who have meningococcal disease remains controversial.

Numerous investigators have attempted to predict the outcome for individual patients who have meningococcal disease based on laboratory and clinical data. In 1966, Stiehm and Damrosch developed a prognostic score whereby patients who had three or more symptoms (the presence of petechiae for fewer than 12 hours before admission, shock, the absence of meningitis, normal or low white blood cell counts, or normal or low erythrocyte sedimentation rates) had fatality rates of 85% or greater when the score was validated. The Glasgow Meningococcal Septicemia Prognostic Score was developed in 1987 (Table 366-2) and is designed for rapid bedside assessment without the need for multiple laboratory tests. Points are assigned for shock, a skin-to-rectal temperature differential of greater than 3°C, a pediatric-modified coma scale score of less than 8, absence of meningismus, an extending purpuric rash, deterioration in the hour before scoring, and a base deficit greater than 8. A score of 10 or greater has a positive predictive value of 87.5% and a negative predictive value of 100%. Although multiple scoring systems have been developed for invasive meningococcal disease, the Glasgow Meningococcal Septicemia Prognostic Score continues to perform well in clinical studies compared with other methods. In general, these scoring systems are used to determine which patients might benefit from more aggressive or experimental therapies and to help evaluate the usefulness of newer treatments.

## COMPLICATIONS

About half of children who survive meningococcal disease recover completely; 15% to 57% of patients, however, develop a complication of infection that may be categorized broadly as suppurative, neurologic, ischemic, or allergic. The suppurative complications include subdural effusions, subdural empyema, and acute suppurative arthritis. Suppurative complications occur in about 9% of children. Deafness occurs in 2% to 6% with significant numbers of adolescents reporting hearing or speech problems after recovering

from meningococcal disease (12% and 13%, respectively). Other neurologic sequelae noted by adolescent survivors include vertigo in 17% and seizures in 2%. Adolescents also report more subtle long-term consequences of meningococcal disease, including a decreased quality of life, increased depression and fatigue, decreased educational achievement, and decreased social support compared with matched controls up to 3 years after their disease.

The percentage of survivors who have ischemic complications such as gangrenous necrosis of the skin or extremities requiring skin grafting or amputation varies from 3% to 20%. Arthritis and pericarditis are also common sequelae of meningococcal infection, reported in 4% to 10% of pediatric cases. These complications are thought to be caused by an allergic phenomenon with immune complex deposition rather than a direct invasion of the heart or joints by the organism. Allergic arthritis and pericarditis are late in onset and more common in adults than in children. The symptoms usually are self-limited, and specific therapy is generally not required; however, drainage of pericardial or joint fluid occasionally is necessary.

Although not a true complication, complement deficiency has been reported in about 15% of adolescents and children who have meningococcal infection and is a known risk factor for the development of disease. These patients are at high risk for recurrent episodes of invasive infection. Based on this information, screening for complement deficiencies with a total hemolytic complement assay should be considered in any pediatric patient who has meningococemia.

## DISEASE CONTROL AND PREVENTION

Antimicrobial chemoprophylaxis is an integral component in the control of invasive meningococcal disease. Household, child care, and preschool contacts of patients who have invasive disease have a rate of infection about 100 to 800 times that of the general population. In addition, 50% of secondary cases occur within 5 days of the index case and 70% within 1 week. Rifampin is highly effective in eliminating carriage of the meningococcus from the nasopharynx. The American Academy of Pediatrics recommends that all household, child care, or preschool contacts or anyone directly exposed to a

patient's secretions be given chemoprophylaxis within 24 hours of recognizing the primary case. The most commonly used drug for children is rifampin at a dose of 10 mg/kg per dose (maximal adult dose is 600 mg) every 12 hours for 2 days for children older than 1 month of age and 5 mg/kg per dose every 12 hours for 2 days for infants younger than 1 month of age (Table 366-3).

Alternative agents that have been proved effective in chemoprophylaxis include ceftriaxone, ciprofloxacin, and azithromycin. Although ceftriaxone is not recommended for widespread chemoprophylactic use, a single 250-mg intramuscular dose has the advantage of being safe for pregnant women. Ciprofloxacin is not approved for children or pregnant women for the prevention of meningococcal disease, but it can be used in older adolescents and adults as a single oral 500-mg dose. However, resistance of *N meningitidis* to ciprofloxacin has been reported in the United States at low levels. Despite this finding, ciprofloxacin remains a useful drug for chemoprophylaxis in areas with only a single episode of resistance.

Vaccination is an additional cornerstone of meningococcal disease prevention. Two quadrivalent meningococcal polysaccharide-protein conjugate vaccines are licensed for use in individuals from 11 to 55 years of age, MCV4 and MenACWY-CRM. Routine immunization with a conjugate vaccine is recommended for

all children aged 11 to 18 years and for those aged 2 to 55 years with an increased risk for meningococcal disease. Both vaccines contain purified capsular polysaccharide of serogroups A, C, Y, and W-135 conjugated to a protein carrier. The conjugated protein elicits a T-cell-dependent antibody response and induces immunologic memory. In a trial comparing meningococcal polysaccharide vaccine with MCV4, among more than 800 children aged 11 to 18 years who received conjugate vaccine, 82% to 97% of children achieved 4-fold or greater increases in serum bactericidal antibody titers, and 98.6% to 99.8% achieved protective levels to all 4 serogroups. The newer MenACWY-CRM vaccine is also highly immunogenic, inducing higher bactericidal antibody titers to the 4 serogroups compared with MCV4 in subjects from 11 to 18 years of age. Additionally, MenACWY-CRM vaccine has been shown to elicit protective levels of bactericidal antibody following infant immunization, suggesting that this vaccine may be useful in the first year of life. Adverse reactions to both conjugate vaccines are mild and infrequent and are usually limited to local reactions and fever.

Unfortunately, no vaccine is currently available in the United States for protection from group B meningococcal disease. The group B capsule is not strongly immunogenic in humans and has been found to share cross-reacting antigens with human neural tissue.

**Table 366-3**

### Recommended Chemoprophylaxis Regimens for High-Risk Contacts and People with Invasive Meningococcal Disease

AGE OF INFANTS, CHILDREN, AND ADULTS	DOSE	DURATION	EFFICACY (%)	CAUTIONS
<b>RIFAMPIN<sup>a</sup></b>				
<1 mo	5 mg/kg, orally, every 12 hr	2 days		
≥1 mo	10 mg/kg (maximum 600 mg), orally, every 12 hr	2 days	90-95	Can interfere with efficacy of oral contraceptives and some seizure and anticoagulant medications; can stain soft contact lenses
<b>CEFTRIAXONE</b>				
<15 yr	125 mg, intramuscularly	Single dose	90-95	To decrease pain at injection site, dilute with 1% lidocaine
≥15 yr	250 mg, intramuscularly	Single dose	90-95	To decrease pain at injection site, dilute with 1% lidocaine
<b>CIPROFLOXACIN<sup>a,b</sup></b>				
≥1 mo	20 mg/kg (maximum 500 mg), orally	Single dose	90-95	
<b>AZITHROMYCIN</b>	10 mg/kg (maximum 500 mg)	Single dose	90	Not recommended routinely; equivalent to rifampin for eradication of <i>Neisseria meningitidis</i> from nasopharynx in one study

<sup>a</sup>Not recommended for use in pregnant women.

<sup>b</sup>Use only if fluoroquinolone-resistant strains of *N meningitidis* have not been identified in the community.

Attempts to create broadly protective vaccine by using outer membrane proteins continue.

### WHEN TO REFER

All patients with suspected invasive meningococcal disease should be discussed with both Critical Care and Infectious Disease specialists.

### WHEN TO ADMIT

All patients with suspected invasive meningococcal disease should be admitted to the hospital for full evaluation and treatment.

## Chapter 367

# PHYSICAL ABUSE AND NEGLECT

Howard Dubowitz, MD, MS; Martin A. Finkel, DO

The abuse and neglect (maltreatment) of children are pervasive problems, with short- and long-term physical and mental health and social consequences. Primary care physicians have an important role in helping address this problem. In addition to their responsibility to identify maltreated children and help ensure their protection and health, primary care physicians can also play vital roles related to prevention, treatment, and advocacy.

## DEFINITIONS

*Abuse* is generally defined as acts of commission, and *neglect* as acts of omission. To guide the states, the federal government defines child abuse as “any recent act or failure to act on the part of a parent or caretaker, which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm.” Children may be in situations without an imminent risk for serious harm, although there may be risk for such harm in the months or years ahead. Most state laws include potential harm, and any interest in preventing abuse or neglect requires intervening when potential harm is a concern.

Predicting potential harm, however, is inherently difficult. Two aspects should be considered. One is the likelihood of harm; the other is the severity. In general, even a small likelihood of serious harm is worrisome, such as leaving an infant alone in a bathtub. Conversely, a greater likelihood of minor harm is often construed as less concerning. The history may be helpful. For example, a child with severe asthma may be at substantial risk for returning to the intensive care unit if she does not adhere to the treatment plan.

## Physical Abuse

Physical abuse includes beating, slapping, shaking, scalding, and biting that may injure any part of the body. Given that corporal punishment is widely accepted in the United States, what is the threshold for considering spanking or hitting as abusive? One approach is to consider any injury beyond transient redness lasting more than 24 hours as abuse. If parents do spank a child, it should be limited to the buttocks, over clothing, and should never involve the head and neck. When parents use objects other than a hand, the potential for serious harm increases. Acts of serious violence (eg, throwing an object at a child, slapping an

infant's face) should also be seen as abusive even if no injury ensues; significant risk for harm exists.

It can be argued that all physical punishment should be construed as abusive, given the substantial evidence on its short- and long-term potential harm. One review of more than 300 original articles on corporal punishment found many associations with problems in childhood (eg, aggression and delinquent and antisocial behavior) as well as in adulthood (eg, aggression, criminal and antisocial behavior, mental health problems, and abuse of one's own child and spouse).

### Child Neglect

Child neglect refers to parental or caregiver omissions in care regarding health care, education, supervision, protection from hazards in the environment, physical needs (eg, clothing, food), and emotional support that result in actual or potential harm. An alternative view to focusing on caregiver omissions in care is to instead consider the basic needs of children (eg, adequate food, clothing, shelter, health care, education, nurturance); neglect occurs when a basic need is not adequately met and results in actual or potential harm, whatever the reasons. Several state laws exclude neglect when it is thought to be primarily a result of poverty. Although state laws generally include potential harm, child protective services (CPS) often gets involved only after actual harm has occurred.

### Psychological Maltreatment

*Psychological maltreatment* and *emotional maltreatment* are interchangeable terms that reflect acts both of commission and omission that impair children's well-being and can be evidenced by emotional distress and maladaptive behaviors. Psychologically abusive behaviors by caregivers include spurning, terrorizing, isolating, exploiting or corrupting, and denying mental health, medical, or emotional care. Such caregiver behaviors may be extremely harmful, resulting in depression, anxiety, estrangement, poor self-esteem, and lack of empathy. There are, however, few or no physical indicators, and CPS generally does not become

involved unless the maltreatment is accompanied by other forms of abuse. Primary care physicians suspecting psychological maltreatment have a role in engaging CPS and facilitating an appropriate mental health assessment, which is essential to understanding a child's experience and accessing appropriate treatment. All forms of abuse and neglect should be presumed to have an associated adverse psychological effect. For example, long after bruises fade and fractures heal, emotional scars may endure.

### Sexual Abuse

Please refer to Chapter 329, Sexual Abuse of Children.

## INCIDENCE

In 2012, 3.4 million reports were made to CPS at a rate of 46 per 1,000 children. Two million (62%) of these reports were considered appropriate for investigation. The highest rate of maltreatment, 21.9 per 1,000, was for children aged 0 to 1 years. Boys accounted for 49% of victims. The rate for black children was almost twice that for white children (20.4 vs 11.0 per 1,000). This rate is likely caused, in part, by professional bias in reporting low-income and minority families for maltreatment. Professionals accounted for 59% of all reports investigated by CPS. Just 18% of investigations were substantiated. Seventy-three percent involved neglect, 18% physical abuse, 9% sexual abuse, 5% emotional abuse, and 3% medical neglect. Reported cases reflect only the tip of the iceberg; child abuse and neglect usually occur behind closed doors and are often not detected.

In 2012, 1,593 children died from abuse and neglect, a national rate of 2.2 per 100,000 children. Nearly three-fourths (70%) of fatalities were in children younger than 3 years. Boys had a higher fatality rate than girls, 2.5 versus 1.9 per 100,000. Four-fifths of child fatalities were caused by one or both parents.

## ETIOLOGY

Child maltreatment seldom has a single cause; rather, multiple and interacting risk factors usually exist at 4 levels, shown in Table 367-1. For example, a single

**Table 367-1** Major Risk Factors for Physical Abuse and Neglect

CHILD	PARENT	FAMILY	COMMUNITY/SOCIETY
Prematurity	Young/teenage	Intimate partner (domestic) violence	Violent neighborhood
"Difficult" temperament	Depression and other mental health problems	Single parent, uninvolved father	Limited access to child care
Chronic illness	Substance abuse	Poverty	Few services that support parents, families
Emotional and behavioral problems	Poor impulse control and anger management skills	Unemployment	Limited government "safety net"
Developmental disability	History of abuse as a child	Nonbiologically related adult living in the home	
Physical disability	Lack of social support		
Multiple gestation	Single parent		
	Limited knowledge of child development and unreasonable expectations		

parent with a severely asthmatic child, living in a dangerous neighborhood and with few supports, may be at relatively high risk for neglect or abuse. Although poverty and its associated burdens contribute to child maltreatment, children in middle- and high-income families can also be abused and neglected. Pediatricians need to guard against possible biases leading to overdiagnosing maltreatment in low-income families and missing the problem in high-income families.

### Protective Factors

In medicine, the orientation is to identify the pathology or problems. There are, however, invariably also positive or protective factors that help buffer the effect of risk factors. These may be internal to the family, such as a parent's wish for the child to be healthy. They may be external, such as a caring pediatrician or community program. It is valuable to identify and build on protective factors. For example, saying to the parent who has not filled a prescription for his or her severely asthmatic child, if appropriate—"I can see how much you love your daughter, and you don't want her back in this ICU. What can we do to keep her healthy?"—is more likely to be effective than calling attention to what the parent has failed to do for the child. In such ways, protective factors are useful for intervening effectively.

### PREVENTION

In general, medical responses to child maltreatment have been after the fact; preventing the problem is clearly preferable. Primary care physicians can help in several ways. An ongoing relationship in primary care offers opportunities to develop trust and knowledge of a family's circumstances. Astute observation of parent-child interactions can also reveal useful information. Pediatricians generally have excellent rapport with parents and children, and they are seen as authorities on many issues affecting children's health and development. This offers a remarkable entry to understand the child's environment and to intervene.

Naturally, there are limits to what can be achieved in the pediatrician's office, making it necessary to be well informed of community resources. There are well-studied programs such as Nurse-Family Partnership, Triple P, and Circle of Security that support families and can help prevent child abuse and neglect.

### Education and Anticipatory Guidance

Educating parents and children regarding medical conditions helps ensure implementation of the treatment plan and to prevent neglect; older children can increasingly share responsibility for their own care. Possible barriers, such as concerns about a medication's side effects or inability to pay for treatment, should be addressed. Practical strategies such as providing written care plans can help. In addition, anticipatory guidance helps with the challenges of childrearing, diminishing the risk for maltreatment. Interventions that educate parents of newborns about how to approach infant crying and the risks of shaking may help prevent abusive head trauma.

### Screening

Another approach is for pediatricians to identify and help address common risk factors for child maltreatment, such as parental depression, substance abuse, harsh punishment, and intimate partner violence. This fits well within the social history and with the recognition that these problems jeopardize children's health, development, and safety. By providing more comprehensive care, pediatricians can strengthen families, support parents, promote children's well-being, and help prevent abuse and neglect. Regular checkups—focused on prevention—offer excellent opportunities to play this role.

The Safe Environment for Every Kid (SEEK) model has been evaluated in 2 randomized controlled trials showing reduced child maltreatment and harsh punishment. Core components of the model include the SEEK training available online, use of the SEEK Parent Questionnaire to identify targeted problems, parent handouts, and ideally access to a mental health professional. Alternatively, pediatricians can briefly assess and initially manage problems, with office staff facilitating referrals to community resources.

Information obtained directly from children or youth is also important, especially given that separate interviews with teens have become the norm. Sample questions include the following:

- "How do you get along with your parents?"
- "If you're really upset about something, who do you talk to?"
- "Is anyone giving you a hard time at home?" If yes, "how so?"
- "Most kids get punished sometimes. How do you get punished?"
- "Are you sometimes hungry, and there's no food at home?"
- "What do you wish could be different at home?"

### Responding to a Positive Screen

As with the SEEK model, any concerns raised by youth require a brief assessment, initial management, and possible referral for further evaluation or treatment. More frequent office visits can be scheduled to offer support and counseling while monitoring the situation. Other key family members (eg, fathers) might be invited to participate, thereby encouraging informal support. Practices might arrange parent groups through which problems and solutions are shared. Primary care physicians also need to recognize their limitations and when other professional intervention is indicated, making knowledge of community resources essential.

Finally, many of the problems underpinning child maltreatment require policies and programs to enhance families' abilities to care for their children. Examples include improving access to health care including mental health and dental care; extending food benefit programs such as the Women, Infants, and Children (WIC) Nutrition Program and the Supplemental Nutrition Assistance Program (SNAP); and improving access to community family support centers. Primary care physicians can be effective advocates for such policies and programs.

## EVALUATION

Pediatricians are accustomed to consulting with subspecialists; pediatric experts in child maltreatment (child abuse pediatricians, or CAPs) should be viewed this way. Pediatricians should identify a local specialist in child maltreatment with whom they can consult. When the pediatrician's concern meets jurisdictional or agency criteria for suspected maltreatment, there is a statutory requirement to refer to CPS. The threshold for reporting is a *reason to believe* standard rather than certainty. If uncertain about whether a situation meets the threshold to report, the pediatrician can call CPS, share concerns, and seek advice. CPS may have information on past or current involvement. Their investigation can add helpful information on the home and family situation.

No single discipline has all the information about what a child might have experienced—hence the need for working in an interdisciplinary manner. The primary care pediatrician cannot typically directly access an interdisciplinary team, but the information he or she provides to CPS can be of great value to the team. Interdisciplinary practice provides the optimal approach to the complex problem of child maltreatment. Pediatricians focus on the medical piece of the puzzle; colleagues from mental health, CPS, law enforcement, and schools can add important perspectives and information. Interdisciplinary evaluation is optimal not only for determining whether maltreatment has occurred but also for clarifying the needs of the child and family. For example, law enforcement officers or CPS workers who have visited the home may provide useful information on the circumstances surrounding an injury (eg, the temperature of the hot water thought to have caused a child's burn) and insight into the functioning of a family. Ultimately the collective insight of several professionals is generally required to substantiate abuse, and this collaboration results in shared decision-making and liability in these complex cases.

Hearing about or seeing the results of child abuse can create a visceral response, and pediatricians need to modulate their feelings and maintain objectivity. It is best to avoid being accusatory or confrontational. Being a concerned, helping professional with a mandate to protect children will best serve the child's and the family's interests. Pediatricians can cautiously empathize, "What you've told me sounds really tough!" Most maltreated children are not removed from their caregivers. Maintaining a constructive relationship with the child's parents, without compromising the statutory requirement to report suspected maltreatment, is best.

### Obtaining a History About an Injury

The physical findings may be nonspecific, making the history especially important. A history that does not reasonably explain an injury is key to determining abuse. Caregivers may state that they did not witness the incident, which may be true. Primary care physicians generally think that parents provide an accurate history. Unfortunately, when abuse occurs, there may be deliberate or unconscious motives for not disclosing what happened. Therefore primary care physicians

need to assess carefully the likelihood that the history adequately explains the findings.

Physicians confronted with a child's injury need to decide whether the history reasonably explains the injury. This requires understanding the clinical aspects of trauma and the context in which maltreatment occurs. Carefully considering alternative explanations for the injury is essential. A thorough history is needed, which includes comprehensive psychosocial information, a thorough physical examination, and appropriate laboratory and radiologic studies.

Whenever possible, primary care physicians should obtain separate histories from each of the child's caregivers and from the child. Children can frequently explain how their injuries occurred if approached in a manner that is empathetic and nonjudgmental. Even young children can explain circumstances that lead to an injury. Children and caregivers may be reluctant to be truthful because of unrealistic fears regarding the consequences.

If a child has experienced physical discipline, open-ended questions inviting a narrative might help illuminate a child's experience. Examples include the following:

- "Can you tell me everything about what happened?"
- "Can you tell me what you want to happen?"
- "Are you a perfect child?" In response they may say yes or not always. Then ask: "What does (insert name) do when you're not perfect?" If they respond, "Puts me in time out," then ask, "If time out doesn't work, what happens next?" Children will generally explain what happened.
- "Grown-ups put kids in time out sometimes. If you could put a grown-up in time out, would you do it? What for?"

Yes-or-no questions do not enable the child to provide contextual details that better describe the experience. Encouraging children to express their feelings provides insight into the psychological effect of what occurred. Asking children what they want to happen after they describe physical punishment helps empower children. Most children respond that they just want the hitting to stop.

Leading and suggestive questions should be avoided. Examples include "I heard your dad hit you, right?" or "Did someone hit you there?"

Pediatricians are hampered by not witnessing the scene where an injury occurred. Thus they may need information collected by CPS and law enforcement professionals regarding the circumstances surrounding the injury.

### Physical Examination

Just as great care is needed when obtaining a history, the physical examination must be comprehensive and meticulous, with clear and detailed documentation. Whenever possible, injuries should be photographed, appropriately identifying the child, using a measuring scale providing a permanent and objective record, and enabling second opinions.

### Cutaneous Manifestations of Abuse

#### Bruises

Bruises are the most common manifestation of physical abuse. Primary care physicians often face the

dilemma of whether the bruise was caused by noninflicted (accidental) trauma. Bruising in preambulatory children is rare (2.2%) and should raise concern for abuse. “Cruising” (18%) and walking children (52%) often experience bruises. Noninflicted bruises are characteristically anterior and over bony prominences, such as shins and forehead, usually resulting from falls. Well-padded areas such as the buttocks, cheeks, and thighs are less likely to bruise during most activities, as are the neck, ears, and genitalia. Bruises of these areas suggest abuse. Some bruises carry the imprint of the implement used. For example, circumferential marks around the wrists, ankles, and neck may result from squeezing, grabbing, or ligatures.

Physicians may be asked to age a bruise to identify the likely perpetrator, corroborate the explanation for injuries, or confirm that injuries occurred at different times. However, precisely dating bruises is very difficult. Many factors determine the color of a bruise, including the depth of the injury, location, force employed, vascularity of the tissues, time since the injury, skin color, and ambient lighting. Previously published tables on dating bruises should be ignored.

Although bruises are the most common manifestation of physical abuse, there may be an underlying medical explanation, such as blood dyscrasias or connective tissue disorders. The family or child’s history or examination usually provides clues to these conditions. Henoch-Schönlein purpura, the most common vasculitis in young children, may be confused with abuse. If an underlying bleeding disorder is suspected, then a platelet count, prothrombin time, international normalized ratio (the ratio of a patient’s prothrombin time to a normal [control] sample, raised to the power of the International Sensitivity Index [ISI]), and partial thromboplastin time should be obtained. However, the pattern and location of bruises caused by abuse are usually different from those resulting from a coagulopathy. The presence of a medical disorder does not preclude possible abuse. Birthmarks and Mongolian spots can be confused with bruises; however, these skin markings are not tender and do not rapidly change color or size.

Cultural practices need to be considered in the differential diagnosis. Cao Gio, commonly known as *coining*, is a Southeast Asian folkloric therapy. A coin or other hard object is vigorously rubbed on the skin in a linear fashion, causing petechiae or purpura. Cupping is another approach popular in the Middle East. A heated glass is applied to the skin, often on the back. As it cools, a vacuum results, leading to perfectly circular bruises. The context is important, and such circumstances should not be considered abusive.

### Bites

Bites have a characteristic pattern of 1 or 2 opposing arches with multiple bruises. They can be inflicted by an adult, another child, an animal, or the patient. Bites by a child (younger than approximately 8 years with primary teeth) typically have a distance of less than 2.5 cm between the canines—often the most prominent bruises. Animal bites vary and usually have narrower arches than human bites and are often deep. Self-inflicted bites are on accessible areas, particularly the

hands. Adult bites raise concern for abuse. Multiple bites by another child suggest inadequate supervision and neglect. If there is a question as to whether the bruise represents a bite and whose bite it might be, it is important to photograph the bite with either an American Board of Forensic Odontology ruler if available or a known-sized object such as a coin. A photograph obtained in either way helps a forensic odontologist identify the source.

### Burns

Childhood burns may be caused by abuse (Box 367-1). More commonly, burns involve inadequate supervision or neglect, such as when a young child topples something on the stove. Scalding burns may be from immersion or splash. Immersion burns, when a child is forcibly held in hot water, have clear delineation between the burned and the healthy skin. The depth of the burn may be uniform and may have a sock or glove distribution. In many instances, no splash marks are evident, as might be expected if a child inadvertently encountered hot water. Symmetrical burns are especially suggestive of abuse, as are burns of the buttocks and perineum. A splash burn may be the result of abuse but more commonly results from accidental contact with a hot liquid. Caustic substances such as household cleaning solutions, pool chemicals, battery fluid, bleach, and drain cleaners are examples of substances that can burn on contact. Laxatives containing Senna or sorbitol can result in perianal blisters and skin breakdown in children in diapers.

Burns from hot objects such as curling irons, radiators, steam irons, metal grids, hot knives, and cigarettes have shapes that reflect the object. A child is likely to try to escape from a hot object; thus burns that are extensive and deep reflect more than fleeting contact and are suggestive of abuse. Other causes of inflicted abusive burns can involve hair dryers, microwave ovens, and stun guns.

Neglect frequently contributes to childhood burns. Children home alone may be burned in house fires. A parent compromised by prescription or nonprescription drugs or alcohol may be unable to effectively intervene if a fire develops. Children explore their environment; for example, unattended pots on the stove with projecting handles present a hazard. Liquids cool as they flow downward so that the burn is

#### BOX 367-1 Characteristics of Burns Suggestive of Abuse

- History that does not adequately explain the burn
- Burn reflecting shape of an object
- Multiple burn sites
- Deep or extensive burn
- Extremities on both sides burned, such as a glove or sock pattern
- Clear, regular edge, uniform depth, no splash marks
- Other history or examination findings suggestive of abuse

most severe and broad superiorly. If the child is wearing a diaper or clothing, hot water may soak into the fabric and cause burns worse than otherwise might be expected, with patterns that follow the child's clothing. Children may stick objects into an electrical outlet, perhaps causing internal (eg, cardiac) injury and a burn where the current exits the body. Burns may occur from electric water heaters being set much higher than the recommended 120 degrees.

Several conditions may mimic abusive burns, such as brushing against a hot radiator, car seat burns, hemangiomas, and folk remedies such as moxibustion. Impetigo may resemble cigarette burns. Cigarette burns are usually 7 to 10 mm in diameter, whereas impetigo has lesions of varying sizes. Noninflicted cigarette burns are usually oval and superficial.

Concluding whether a burn was inflicted depends on the history, burn pattern, and the child's capabilities. A delay in seeking health care may be the result of the burn initially appearing minor, before blistering or becoming infected. This circumstance may represent reasonable behavior albeit an unfortunate momentary lapse in supervision and should not be automatically deemed neglectful. A home visit to investigate the scene where the child was burned is necessary to clarify the circumstances surrounding the burn (eg, testing the water temperature). Severe burns can lead to lifelong scarring and serious psychosocial sequelae. Prevention is key, such as setting hot water cylinders at 120°F.

### Skeletal Trauma

Any bone can be fractured as a result of abuse; however, fractures strongly suggestive of abuse are classic metaphyseal lesions (ie, corner fractures at ends of long bones), posterior rib fractures, and fractures of the scapula, sternum, and spinous processes, especially in young children. These fractures all require more force than would be expected from a minor fall or routine handling and activities. Few fractures are pathognomonic of abuse, however, and all must be considered in light of the history. It is always necessary to assess whether the history plausibly explains the fracture. For example, a history that a child walked comfortably with a displaced femoral fracture is unlikely to be truthful.

The history begins with a careful family history to probe possible underlying genetic bone conditions, such as osteogenesis imperfecta. Questions should cover multiple or frequent fractures, hearing difficulties, unusual flexibility, and teeth abnormalities. These should also be asked with regard to the child. A detailed history is needed regarding the presenting injury: whether the fall was witnessed, by whom, how the child fell, from what height, onto what surface, whether there were objects in the way (eg, toy truck on the floor), how the child behaved after the fall, what the parents did, the psychosocial circumstances, and any any past history of trauma.

Multiple fractures, especially if at different stages of healing, are suspicious for abuse. The possibility of an increased susceptibility to fractures caused by an underlying bone condition needs to be considered. These conditions include osteopenia of prematurity,

osteogenesis imperfecta, metabolic and nutritional disorders (eg, scurvy, rickets), renal osteodystrophy, osteomyelitis, congenital syphilis, and neoplasia. The presence of a bone disorder, however, does not exclude the possibility of abuse.

Subperiosteal new bone formation is a nonspecific finding and can be seen in infectious and metabolic disorders or may result from trauma and thus may suggest abuse. In young infants, new bone formation may be a normal physiologic finding and is usually bilateral, symmetrical, and less than 2 mm wide.

Rib fractures in young children rarely present clinically. They are mostly diagnosed on chest radiographs obtained for another reason. Both rib and sternal fractures rarely result from cardiopulmonary resuscitation, even when performed by untrained adults. Rib fractures are likely caused by excessive compression of a young child's thorax. They are very rarely caused by birth trauma; 1 study of nearly 35,000 infants found no such injuries. Sternal fractures are mostly seen after car crashes; without such a history, they likely indicate the child was stomped on. Clavicular, femoral, supracondylar humeral, and distal extremity fractures in children older than 2 years are most likely not inflicted, unless they are multiple or accompanied by other signs of abuse. With increasing mobility and running, toddlers can fall with enough rotational force to cause a spiral, femoral fracture, meaning such fractures are not specific to abuse. Fractures of long bones, spiral and otherwise, in nonambulatory infants, however, are highly suggestive of abuse. In addition, abuse is a concern when there are other injuries including bruising, other than from high-energy impacts such as a motor vehicle crash.

Skull fractures are the most common type of fracture in children younger than 2 years, most commonly resulting from short falls from 3 to 6 feet. Of note, only 1% to 2% of children experiencing such falls fracture their skulls, usually a simple linear fracture of the parietal bone, associated with hitting a hard object such as the floor or table corner. Complex, depressed, bilateral, or basilar skull fractures require greater biomechanical forces; without a plausible history, they are suspicious for abuse.

### Radiologic Studies

A skeletal survey should be routine in children younger than 2 years with a fracture, especially if a possibility of abuse exists. When fractures are identified or concerns persist despite no findings on a skeletal survey, follow-up surveys 2 weeks later have been found to identify new previously missed occult fractures. In children between 2 and 5 years of age, the usefulness of a skeletal survey depends on the specific circumstances. *Babygrams* (1 or 2 radiographs of the entire body) do not provide adequate visualization of the entire skeleton and should be avoided. If the survey is negative but concern for an occult injury remains, a radionuclide bone scan should be performed. A scan will be generally positive for fracture within 24 to 48 hours after an injury and will remain positive throughout the stage of callous formation. Standards for a skeletal survey and other forms of imaging have been developed by the American College of Radiology.

### Timing of Injury

In corroborating the history and the injury, the age of the fracture can be crudely estimated. Soft tissue swelling generally subsides in 2 to 21 days. Periosteal new bone can be seen as early as 4 days after injury but up to 21 days later. Loss of definition of the fracture line occurs between 10 and 21 days. A soft callus on a long bone can first be observed 10 days after an injury. A hard callus is evident between 14 and 90 days. The child's age, the type of bone, and the nature of the fracture influence the healing process. The remodeling of bone can continue until epiphyseal closure. These time frames are shorter in infancy and longer when the child has poor nutritional status or a chronic underlying disease. Fractures of flat bones such as the skull do not form a callus and cannot be aged.

## Central Nervous System

### Epidemiology

The rate of inflicted head trauma has been estimated at between 16 and 34 per 100,000 infants per year. Risk factors include male infants and socioeconomic and other stressors, but not race or ethnicity. Of all inflicted injuries, those to the central nervous system result in the most significant morbidity and mortality. Long labeled "shaken baby syndrome," the recommended term is now *abusive head trauma* (AHT). This reflects our understanding that often both shaking and direct trauma are involved.

### Mechanism

Infants, with their poor neck muscle tone and relatively large heads, are most vulnerable to AHT. Shaking is considered to exert severe, repetitive, and often rotational forces injuring the brain as it moves within the skull. This may cause acute concussion, diffuse traumatic axonal injury, nonfocal acute subdural bleed, contusions, and brain lacerations. Direct contact injury may result from punching, slapping, or striking the child's head against a hard surface. Injuries include bruising, lacerations, abrasions, and soft tissue swelling of the head or face, subgaleal bleeds or cephalohematomas, skull fractures, and associated intracranial pathology related to skull deformation. It is estimated that the forces involved far exceed those occurring during normal activities and play, such as gently tossing an infant into the air and catching him or her.

### History

As with abuse in general, there is seldom a forthright account when AHT is involved. Instead, common histories include finding the previously healthy baby suddenly unresponsive or not breathing, a choking episode while feeding, a minor bump against a hard surface, or a short fall off a sofa or changing table. Multiple studies have demonstrated that such falls rarely result in skull fractures and very rarely cause significant intracranial pathology. Such histories do not plausibly explain the clinical picture of an infant with severe neurologic symptoms.

### Clinical Presentation

The clinical picture can range from mild vague symptoms to coma or respiratory arrest to death. Lucid

periods after severe head injuries are rarely seen with witnessed trauma (eg, motor vehicle crashes). Most infants lose consciousness at the time of injury; even those who remain lucid are still symptomatic. Children with less severe injuries may initially have mild symptoms, such as vomiting or irritability, before symptoms become worse.

There is naturally a spectrum of severity, and "minor" AHT may cause no overt signs or symptoms or a subtle presentation that may be missed. Subtle findings include unexplained lethargy, vomiting without fever or diarrhea, and inconsolable crying. One study of children younger than 3 years with AHT found that one-third had previously had medical encounters in which the possibility of AHT should have been considered but was missed; 28% suffered subsequent AHT. Factors associated with missed instances were normal respiration, no seizures, no facial or soft tissue injuries, and a white family with 2 caregivers.

As with fractures, the history should include a detailed account of whether any trauma was witnessed, by whom, whether and how the child fell, from what height, onto what surface, whether there were objects in the way, how the child behaved after the fall, what the parents did, the psychosocial circumstances and any past history of trauma. With multiple caregivers, obtaining separate histories is recommended. An investigation by law enforcement of the site where the injury allegedly occurred is valuable.

The physical examination may show cutaneous or other injuries, or no external sign of trauma. Bruises from attempted strangulation may be visible on the neck. In contrast, choking or suffocation may result in asphyxia and hypoxic brain injury, often with no or minimal external signs. A very thorough examination is critical. For example, there may be injuries inside the mouth or blood behind the tympanic membrane. A careful neurologic examination is needed, including coma scores. Associated cutaneous, visceral, or skeletal findings suggestive of abuse, in the absence of readily verifiable major noninflicted trauma, add to the likelihood that the head trauma was abusive.

Further evaluation including a pediatric ophthalmologic examination, laboratory testing, and radiologic studies may reveal occult trauma. Subdural hematomas, retinal hemorrhages, and diffuse axonal injury, although not exclusively caused by AHT, should always raise the question of AHT.

Subdural hematomas are commonly present, caused by shearing of the bridging veins. Subarachnoid bleeds are less common, and intraparenchymal hemorrhages are rare in AHT.

Retinal hemorrhages are a key marker of AHT. Whenever AHT is considered, a dilated indirect ophthalmologic examination by a pediatric ophthalmologist should be performed. If possible, photographic documentation should be obtained. Although retinal hemorrhages are found in other conditions, hemorrhages that are bilateral and extensive, involve multiple layers, and extend to the periphery—beyond the neonatal period and in the absence of a known medical cause—are most often caused by AHT. Severe noninflicted head trauma rarely results in retinal hemorrhages; when this does occur, the hemorrhages

tend to be few in number and confined to the posterior pole. The indirect trauma, most commonly caused by repeated acceleration-deceleration from shaking, seems responsible for extensive retinal and vitreous hemorrhages. It is not possible to estimate when the injury occurred based on the appearance of retinal hemorrhages.

Other causes of retinal hemorrhages include coagulopathy, leukemia, retinal diseases, carbon monoxide poisoning, and metabolic disorders such as glutaric aciduria. Birth-related retinal hemorrhages are very common, but superficial (*flame*) and deeper intraretinal (*dot* or *blot*) hemorrhages resolve by 1 and 6 weeks, respectively. A severe accidental life-threatening direct crush injury to the head can rarely cause an extensive hemorrhagic retinopathy. Cardiopulmonary resuscitation rarely, if ever, causes retinal hemorrhage in infants and young children, and, if so, there may be very few hemorrhages near the optic nerve. Hemoglobinopathies, diabetes mellitus, routine play, minor accidental head trauma, and vaccinations do not seem to cause retinal hemorrhage in infants. Almost all of the medical causes of retinal hemorrhage are readily diagnosed based on history, eye examination, full physical examination, and, when indicated, laboratory testing.

Another ocular finding that points strongly to abuse is traumatic retinoschisis. The retinal layers are sheared apart as a result of traction from the repeatedly accelerating-decelerating vitreous gel to which it is firmly attached. Blood accumulates between the layers. Direct trauma to the orbital region may result in corneal abrasions, subconjunctival hemorrhages, hyphema, globe rupture, and periorbital edema or ecchymosis. The postmortem examination may demonstrate posterior orbital hemorrhage and intraorbital optic nerve injury, helping differentiate noninflicted head injury from AHT.

In summary, the diagnosis of AHT is made by a careful integration of the history, examination findings, ophthalmologic consultation, and results of laboratory and radiologic studies (see Box 367-2). Alternative explanations need to be thoroughly probed.

### Orofacial Injuries

Injuries to the head, neck, and oral cavity may be seen in physically abused children. Soft tissue injuries to the upper lip or the frenulum and palate are seen in forced feeding of an infant but can also occur when a toddler trips, especially with a hard object in the child's mouth. The forceful introduction of hot or caustic liquid into a child's mouth may result in intraoral mucosal injury. Intraoral injuries represent 11% of "sentinel injuries"—relatively minor injuries that may predict more serious ones. Noninflicted trauma to the forehead, lower lip, chin, and nose is common in toddlers and is generally accompanied by a history of an accidental fall. Dentists can identify orofacial and intraoral injuries such as frenulum tears, palatal trauma, and fractured teeth. Their consultation should be considered in children with head trauma.

Blunt trauma to the ear may produce subperichondrial hematoma and intracranial injury resulting from rotational acceleration of the head. Accidental injuries of the ear are rare. A slap to the face may leave a hand

### BOX 367-2 Evaluation of Children With Possible Abusive Head Trauma

1. As with the rest of medicine, a differential diagnosis needs to be developed and plausible explanations fully probed.
2. Obtain head computed tomography (CT) scan (unenhanced).
3. Consider magnetic resonance imaging (MRI) of the head to help clarify extra-axial fluid, determine timing of injuries, assess parenchymal injury, and identify vascular anomalies. MRIs should be with T1- and T2-weighted images, different susceptibility-weighted sequences, and FLAIR sequences.
4. Consider magnetic resonance angiography and venography if a vascular anomaly is suspected.
5. A skeletal survey should be routine.
6. Check complete blood count and platelets.
7. Check liver and pancreatic enzymes. In addition, consider CT scans of the abdomen and thorax to help identify occult thoracic and abdominal injuries.
8. Consider obtaining additional laboratory tests that assist in identifying metabolic diseases such as glutaric aciduria type 1 or conditions such as osteogenesis imperfecta. These conditions are rare, but they should be obtained depending on the clinical circumstances.
9. Consultation with a child abuse pediatrician is recommended.

Derived from Kemp AM. Abusive head trauma: recognition and the essential investigation. *Arch Dis Child Educ Pract Ed.* 2011;96(6):202–208.

imprint, but even more importantly may cause injuries within the head and neck. Any blow to the head can also have significant psychological consequences.

Long-term dental neglect may result in multiple dental caries, abscess formation and risk for septicemia, eating difficulties, chronic pain, and periodontal infection.

### Abdominal Trauma

Abdominal trauma accounts for significant morbidity and mortality in abused children. Young children are especially vulnerable because of their relatively large abdomens and lax abdominal musculature. Hollow organs can be ruptured by a blow or kick. Solid organs such as the pancreas, which can be compressed against the spine when the abdomen is struck, can be injured. Indeed, any of the abdominal organs may be injured because of abuse. Intra-abdominal bleeding may result from trauma to an organ or shearing of the vascular supply. Children may have cardiovascular failure or an acute abdomen, often after a delay in care. Bilious vomiting in a young child without fever or peritoneal irritation suggests a duodenal hematoma, usually a result of abuse and acute in onset.

The manifestations of abdominal trauma are often subtle, even with severe injuries. Subclinical injuries can be identified by elevated liver and pancreatic enzymes reflecting injury not evident on imaging or examination. Bruising of the abdominal wall is

### BOX 367-3 Manifestations of Possible Neglect

Neglect may manifest in many ways. Most commonly, pediatricians encounter the following:

- *Unmet physical needs* (eg, nonadherence to treatment, delay in seeking health care, inadequate food or clothing)
- *Inadequate supervision* (eg, recurring injuries or ingestions, exposure to environmental hazards—in and out of the home, poor hygiene and sanitation)
- *Inattention to cognitive needs* (eg, little stimulation at home, not attending to child's learning or special educational needs)
- *Inadequate attention to emotional needs* (eg, not showing affection, not being supportive at times of need, not enabling mental health care for serious problems)

unusual, and symptoms may evolve slowly. Delayed perforation may occur days after the injury, and bowel strictures or a pancreatic pseudocyst may occur weeks or months later.

Primary care physicians should consider screening for occult abdominal trauma when other evidence of physical abuse exists. Screening should include urinalysis for blood and liver and pancreatic enzyme levels. An abdominal ultrasound should also be considered, although computed tomography is preferable for detecting trauma to solid organs. Children with abdominal injuries resulting from abuse may also have fractures and head injuries; these too should be considered. Noninflicted mechanisms may apply, such as a bicycle handlebar injury, but caution is needed in accepting unlikely explanations.

### Child Neglect

Neglect is the most prevalent form of child maltreatment, with potentially severe and long-lasting sequelae. Physicians may encounter several manifestations of possible neglect (Box 367-3). Initial questions to ask oneself include, "Is this neglect?" and "Have the circumstances harmed the child, or jeopardized the child's health and safety?" For example, adherence to treatment may be suboptimal without clearly impairing a child's health, or it may be life threatening. Inadequacies in the care children receive fall along a continuum, requiring a range of responses tailored to the individual situation.

Pediatricians need to be familiar with their state laws defining child abuse and neglect and the mandatory reporting requirements. For example, most states include the risk for serious harm in their neglect definition. A complementary approach is to focus on children's basic needs; when 1 or more of these needs (eg, adequate food, health care, education) is inadequately met and results in actual or potential harm, the child experiences neglect.

There are advantages to using a child-centered definition of neglect, rather than simply focusing on

parental omissions in care. It fits well with a pediatric mandate to promote children's health, development, and safety. Focusing on the child offers a more constructive way to engage parents, most of whom share an interest in their children's well-being. This approach also encourages consideration of other possible contributors to the neglect, not just a parent's behavior. For example, the physician may not have clearly explained the asthma treatment regimen. Adopting a broader view should lead to consideration of other strategies to help the family take good care of their child.

In most instances, multiple and interacting factors contribute to neglect. For example, consider a young single mother living in a rough neighborhood with her 2 children; one has asthma and the other attention deficit/hyperactivity disorder. She has few supports and faces eviction at the end of the month. Given this highly stressful situation, it is no mystery that she may struggle to cope and filling a prescription may not be a priority.

With this understanding, it is necessary to comprehensively probe what may be underpinning the neglect, recognizing that neglect is really the symptom. The assessment includes understanding possible risk factors—at the levels of child, parent, family, and community. The system of health care should also be examined. Do barriers to health care exist? Does a problematic relationship exist between the pediatrician and the parent or child? Poor adherence to treatment may be the result of not understanding the treatment plan or being worried about a medication's side effects. The pediatrician needs to be cautious not to assume that parents are responsible when a child's medical course is problematic. This may not reflect poor adherence to treatment; the disease may be inherently difficult to control (eg, "brittle diabetes"). In addition to probing for risk factors, strengths and resources (protective factors) should also be assessed; these factors are often crucial to intervening effectively. A parent's interest in keeping a child out of the hospital, for example, may motivate adherence to treatment, as may a child's interest in playing sports. A pediatrician's concern can also be a protective factor, helping to counter the family's challenges.

Pediatricians may encounter other forms of neglect. For example, a child may have inadequate clothing, or the family may be homeless—conditions that can affect children's health. Children may not be enrolled in school. A child's learning may be problematic and the school's response inadequate. A broad view of health and an interest in children's health and development require attention to such facets of their environment. Neglect is a heterogeneous phenomenon that calls for varied responses to address the specific circumstances. Some key principles are outlined later in this chapter.

### OUTCOMES OF CHILD MALTREATMENT

Child maltreatment often has significant short- and long-term medical, mental health, cognitive, and social sequelae. Physically abused children are at risk for behavioral and learning problems, including conduct disorders, aggressive behaviors, decreased cognitive functioning, and poor academic performance. There

may also be internalizing disorders, such as depression, perhaps associated with suicidality and suicide attempts. Neglect is similarly associated with many potential problems. It is apparent that a wide array of health, cognitive, and social problems may relate to physical abuse or neglect. In probing these problems, the possibility of maltreatment needs to be considered. At the same time, none of these problems is specific to abuse or neglect, limiting their usefulness in diagnosing maltreatment.

At the time of an evaluation, a maltreated child may seem to be functioning well. There remains the risk for problems emerging months or years later, and parents and pediatricians need to carefully monitor these children. Even in situations in which all appears satisfactory, a mental health evaluation and possible treatment may help address a child's troubled thoughts and feelings and prevent later problems. Child maltreatment increases the risk for several health risk behaviors and physical and mental health problems in adulthood. Maltreated children are also at risk for becoming maltreating parents. Increasingly, research is showing neurobiologic effects of child maltreatment on the developing brain, with potentially lifelong consequences.

Some children seem to be resilient and may not exhibit sequelae of maltreatment, perhaps owing to protective factors or interventions. The benefits of intervention have been found in even the most severely neglected children, such as those from Romanian orphanages, who were adopted—the earlier the better. Children who were adopted before 6 months of age fared better than those adopted at an older age.

## REPORTING, DOCUMENTATION, AND LEGAL ISSUES

### Reporting

State laws mandate that all physicians report *suspected* child abuse or neglect to the designated public agency. Some states penalize mandated reporters who fail to do so. All reporting statutes supersede any ethical duty to protect confidentiality. As long as the report of suspected abuse or neglect is made in good faith, physicians are immune from both civil and criminal liability. Whether the level of suspicion meets the threshold for reporting is sometimes a judgment call. Pediatricians need not be certain that maltreatment has occurred to make a report; reasonable suspicion is adequate, although *reasonable* is not defined in most regulations. If concerned that a child may have been maltreated, even if uncertain, it is generally necessary to report the concerns to CPS, which in turn decides whether to investigate. A report to CPS may also uncover possible past or current family involvement with the agency. Alternatively an interdisciplinary child protection team or a primary care physician with expertise in this field can provide useful guidance. If in doubt, a call to CPS is recommended.

The decision to report child maltreatment is never easy. Parental response to informing a family that a report will be made may evoke considerable anger or an understanding that reporting provides an opportunity to secure help. In great part the parental

response will depend on how the information is conveyed by the pediatrician and supported by CPS. A recommended approach is to convey one's concern for the child, which is hopefully a concern shared by parents. The basis for the concern should be explained forthrightly but kindly, without being accusatory. Framing the report positively is important to clarifying what happened and to providing helpful services. Some prefer to present the report as a legal obligation, perhaps helping parents accept the physician's role.

It is also useful to explain to parents and children what will likely ensue (eg, a visit from a CPS worker and sometimes a police officer) and what is unlikely. Parents may be anxious about the involvement of CPS, fearing that they might lose their child. Primary care physicians can cautiously reassure parents that CPS is responsible for helping children and families and that, in most instances, children remain with their parents. Even when CPS does not accept a report or when a report is not substantiated, they may offer voluntary supportive services such as food, shelter, homemaker services, and child care. State laws concerning confidentiality and reporting responsibility in suspected child abuse and neglect cases vary; primary care physicians need to know their state's laws, which are available on the Child Welfare Information Gateway Web site at [www.childwelfare.gov](http://www.childwelfare.gov) (state statute search) or by contacting the local CPS agency.

### Documentation

Clear documentation is crucial to the admissibility of all forms of evidence. Verbal and photographic documentation preserves evidence for future reference. The medical history is the verbal evidence; thus it is important to document the concerning circumstances, which may be as important as any physical evidence. Written documentation should include both the key questions asked and the verbatim responses, in quotation marks. This practice enables careful evaluation of the evidence. A clear and comprehensive record may obviate the need to testify. Whenever possible, physical evidence should be documented photographically with an accompanying measuring scale or known size object such as a dime.

### Legal Issues

Whenever a primary care physician is involved in a case of possible abuse or neglect, there is the potential for legal involvement even though few cases are tried in court. Most cases are not criminally prosecuted because of the difficulty of proving who was responsible, or not tried because many cases are plea bargained. Neglect is rarely considered a criminal offense and is seldom prosecuted. Therefore the likelihood of having to testify is generally small. In cases involving custody matters there is an increased likelihood of civil litigation.

Pediatricians who do not specialize in child abuse may testify to provide *facts* about the case, but not be allowed to provide an *expert* opinion regarding the interpretation of those facts. An expert witness is allowed by the court to *opine*, and the jury decides how to weigh the testimony. The medical evidence is 1 piece of the puzzle.

Primary care physicians provide their opinion in their capacity as the treating physician, who obtains the medical history for the purpose of diagnosis and treatment. The medical history may also be admissible in criminal court proceedings as an exception to hearsay rules of evidence. A requirement for admissibility of these out-of-court statements obtained during the history taking is that the patient understands that they are being examined for diagnosis and treatment. A simple explanation of this circumstance and documentation in the medical record help ensure admissibility of a child's statements as an exception to hearsay. This initial history may be crucial to understanding a child's experience. As cases proceed, children may recant their initial statements regarding abuse because of either direct threats or fears of consequences.

### Preparing for Court Testimony

Primary care physicians may be called to testify before a grand jury, juvenile court, or family court or in criminal proceedings. The rules guiding testimony in these various proceedings differ and span the spectrum from relatively informal to highly structured environment of criminal testimony.

The legal system is an adversarial system that can be intimidating. It is common practice for one side to undermine the credibility of witnesses supporting the opposing view. One is well advised to remain calm and not take an attack personally. Preparation with the attorney who issued the subpoena should clarify what can and cannot be said in court.

The grand jury in many states is a preliminary step to indictment. It is an opportunity for the prosecution alone to present its case. A grand jury indictment implies that sufficient evidence exists to justify a trial, and it determines what charges will be filed. If the case proceeds to trial, most primary care physicians who testify do so to describe the medical history and examination findings. A fact witness should not be asked to render an opinion regarding the likelihood of abuse. The court may, however, determine that the primary care physician can testify as an expert, thus allowing an opinion. In some cases, another expert in child maltreatment will be brought by the opposing side to interpret the findings for the court.

A subpoena is often the first notice of the need for involvement in the legal system. Subpoenas are either *subpoena ad testificandum* or *subpoena duces tecum*—the first for actual testimony and the second for supplying records. Different subpoenas may be generated on behalf of the state, the child, and the defendant. When a subpoena is received, the person issuing the subpoena should be asked to clarify what is being requested and to prepare for the legal proceeding. Prosecutors and the court generally try to accommodate primary care physicians' time constraints and schedules.

After a testimony is scheduled, meeting with the attorney who issued the subpoena provides an opportunity to discuss the strengths and weaknesses of the case and review potential questions. It is useful to consider questions that may be posed by the opposing side. If a particular question lacks clarity, it is appropriate to ask for clarification or repetition. Testimony

should educate the jury and judge and thus be presented with a calm and respectful demeanor using plain English that can be easily understood. If technical language is used, terms need to be carefully explained. If asked questions that cannot be answered, one can say, "I don't know."

Regarding testimony, the acronym HELP is helpful: honesty, even-handedness, limits of expertise, and preparation. Adhering to the HELP principles, the physician can effectively assist the court in understanding the evidence.

In the pretrial process of discovery, both the prosecutor and the defense attorney have an opportunity to learn what evidence the other possesses. The defense attorney may contact the examining physician directly to discuss the case as part of discovery. The physician is not legally obligated to comply unless the request is accompanied by a subpoena. Any information a primary care physician has should be considered privileged and confidential and should be disclosed only when the client or legal guardian consents or a subpoena requires such disclosure. In general, state laws grant CPS access to parts of medical records pertaining to a maltreatment report.

An important point to remember is that in criminal trials the defense is responsible for representing the accused; the interests of the child are secondary. Providing a balanced, objective, and defensible opinion is the responsibility of the fact and expert witnesses. This opinion should be the same whether testifying at the request of the prosecution or of the defense. The best way to prepare for testifying in court is to practice good medicine. The child's interests may be represented by an appointed "guardian ad litem" whose responsibility is to act as a fact finder for the court to assist the court in making determinations that serve the best interest of the child in court proceedings.

### TREATMENT

Treatment should address the specific problems contributing to a child's maltreatment and its consequences. Primary care physicians are naturally responsible for helping address any medical problem. Approaching problems of neglect should begin with less intrusive interventions. For example, if an infant's failure to thrive is the result of an error in mixing the formula, parent education and perhaps a visiting nurse should be the initial strategy. At the same time, ensuring a child's safety is paramount. Therefore severe failure to thrive requires hospitalization, and if the contributing factors are particularly serious (eg, a psychotic mother), out-of-home placement may be needed. Thus in neglect situations in which less intrusive efforts have not succeeded or in which the circumstances are moderate or more severe, a report to CPS should be made. CPS can conduct a home assessment that provides valuable insights to develop a fuller picture of the family situation. Physicians can be a valuable liaison between the family and public agencies, and they should make every effort to remain involved after reporting to CPS. Families are typically under great stress after a report, and the involvement of different professionals and agencies can be confusing. With frequent office visits offering support and

guidance, primary care doctors can play an important role in monitoring how a child and family are doing after a report.

In families in which maltreatment occurs, the parents may need to be nurtured before they are able to nurture their children. The parents, even if suspected as perpetrators, remain “patients” of the pediatrician and should be presumed innocent for the purpose of delivery of care to the family unless CPS or the judicial system temporarily or permanently limits their parental rights. Therefore a comprehensive assessment of the child, parents, and family is important to guide appropriate interventions. The use of informal supports such as family members, neighbors, and friends (eg, inviting the father to an office visit) should be encouraged. Families also may need other professional interventions (eg, drug treatment, mental health services); primary care physicians can help with referrals.

The importance of addressing concrete needs should not be overlooked. Accessing nutrition programs, obtaining health insurance, enrolling children in preschool programs, and helping with housing can make a valuable difference. The problems contributing to child maltreatment often require long-term professional support and monitoring; few quick fixes are available.

Although abuse and neglect may lead to physical disability and sometimes death, lasting psychological harm is a major concern. To ensure long-term positive outcomes, children and caregivers benefit especially from evidence-based mental health care. Before receiving a specific form of therapy the child should undergo a pretreatment assessment to determine the effect of the maltreatment and serve as a baseline to assess improvement. Examples of evidence-based mental health treatment modalities are trauma-focused cognitive behavioral therapy, parent-child interaction therapy, and combined parent-child cognitive behavioral therapy. The US DHHS National Registry of Evidence-based Programs and Practices is a resource for finding effective treatment approaches. ([nrepp.samhsa.gov](http://nrepp.samhsa.gov)). The National Child Traumatic Stress Network is also an excellent resource for helping children recover from trauma ([www.nctsn.net](http://www.nctsn.net)).

## ADVOCACY AND PREVENTION

The primary care physician is well positioned to understand the factors that contributed to the child’s maltreatment. Advocating for the best interest of the child and family involves identifying and addressing risk factors and must be done at the levels of individuals, family, and community. At the individual level, an example of advocating on behalf of a child is explaining to a parent that an active toddler is behaving normally and not intentionally challenging the parent. Learning about a parent’s response to a child’s difficult behavior also offers an opportunity to educate the parent regarding appropriate responses. Encouraging a mother to seek help dealing with a violent spouse, saying, “You and your life are very important,” asking about substance abuse and smoking, and assisting parents to seek health insurance for their children are all forms of advocacy.

Physicians advocate on behalf of families when they try to enhance the functioning of families. Encouraging

the involvement of fathers in child care, strengthening ties with extended family, and, in some instances, facilitating family therapy are examples of advocacy. Remaining involved after a report to CPS and helping ensure that appropriate services are provided are other examples.

In the community, physicians can be influential advocates for resources for children and families. These resources may include parenting programs, services for victims of domestic violence and their children, and recreational facilities. Physicians have many opportunities to share their knowledge of children’s physical, developmental, and emotional needs. They can participate on local multidisciplinary child death review teams or as advisors to organizations concerned with child abuse. Engaging in such activities provides opportunities to better understand the issues concerning child maltreatment and to help build safe and nurturing environments for children.

Finally, physicians can play an important role in advocating for policies and programs at the local, state, and national levels that will benefit children and families. Advocacy is needed for community-wide maltreatment prevention efforts at the primary, secondary, and tertiary levels. Primary care physicians can share their knowledge on the health and welfare of children and families with CPS colleagues. This contribution can lead to system changes that are responsive to the needs of children and families. Such efforts may include involvement with state officials along with outreach to legislators and organizations involved in child advocacy. The American Academy of Pediatrics has an office in Washington, DC that is engaged in legislative advocacy on a range of important child health issues and conducts annual training in legislative advocacy. Child maltreatment is a complex problem that has no easy solutions. Through partnerships with colleagues in child protection, mental health, education, and law enforcement, primary care physicians can make a valuable difference in the lives of many children and families. Beyond preventing abuse and neglect, they can promote children’s health, development, and safety in many ways.

## Chapter 368

# PNEUMOTHORAX AND PNEUMOMEDIASTINUM

C. Michelle Zebrack, MD; Susan L. Bratton, MD, MPH

Pneumothorax and pneumomediastinum are uncommon events in healthy children. A pneumothorax is a collection of air in the potential space between the parietal and visceral layers of the pleura. Pneumothoraces are typically classified as spontaneous, traumatic, or iatrogenic. Pneumomediastinum is a condition in which air is present in the mediastinum. The 3 main causes of pneumomediastinum are (1) alveolar rupture; (2) perforation or rupture of the esophagus, trachea, or main bronchi; and (3) dissection of air from the neck or the abdomen. Failure to recognize and properly manage pneumothorax or pneumomediastinum can have serious consequences.

## PNEUMOTHORAX

### Spontaneous Pneumothorax

Spontaneous pneumothoraces occur in the absence of antecedent thoracic trauma and are further subdivided into primary or secondary spontaneous pneumothorax. Primary spontaneous pneumothorax affects patients who do not have *clinically apparent* lung abnormality or an underlying condition known to promote pneumothorax. Secondary spontaneous pneumothorax occurs in the setting of underlying pulmonary disease such as pneumonia, asthma, or cystic fibrosis.

Little is known about the true incidence of spontaneous pneumothorax in children; however, it is infrequent and usually related to underlying lung disease.

### Primary Spontaneous Pneumothorax

Although primary spontaneous pneumothorax is said to occur without a precipitating event or underlying lung disease, patients initially diagnosed with primary spontaneous pneumothorax frequently (76%–100%) have unrecognized lung disease, usually subpleural bullae. The incidence of primary spontaneous pneumothorax in children is not reported, but 1 study documents only 58 children with primary spontaneous pneumothorax in a 20-year period. In adults, the estimated incidence is between 7.4 and 18 cases per 100,000 population per year among men and between 1.2 and 6 cases per 100,000 population per year among women. The typical patient is a tall, thin, male patient between the ages of 10 and 30 years. Smoking increases the risk for primary spontaneous pneumothorax 9-fold among women and 22-fold among men.

### Secondary Spontaneous Pneumothorax

Secondary spontaneous pneumothorax occurs in patients with lung disease. Pediatric incidence related specifically to secondary spontaneous pneumothorax has not been reported, but the adult estimated incidence is 6.3 cases per 100,000 population per year among men and 2 cases per 100,000 population per year among women. Pneumothorax is a known complication of asthma, and, by some estimates, tension pneumothorax is present in almost 30% of patients who die suddenly from asthma. Nearly 3.5% of all patients with cystic fibrosis will experience a pneumothorax, and subsequent pneumothoraces are common. The risk for spontaneous pneumothorax is also increased in various inherited disorders, such as  $\alpha_1$ -antitrypsin deficiency, Marfan syndrome, and Ehlers-Danlos syndrome. Some familial cases without evidence of connective tissue disease do occur. Spontaneous pneumothorax is a well-recognized complication of acquired immunodeficiency syndrome (AIDS) in pediatric patients and is associated with *Pneumocystis carinii* pneumonia. Catamenial pneumothorax, a condition related to endometriosis with diaphragmatic hernia, should be considered in female patients with spontaneous pneumothorax temporally related to menstruation.

### Other Precipitating Factors

Foreign-body ingestion must be considered in any child with an unexplained pneumothorax, particularly children aged 6 months to 6 years. Exposure to loud music has been reported as a precipitating factor in patients with spontaneous pneumothorax. Spontaneous pneumothorax is associated with illicit drug use and may result from attempted jugular or subclavian vessel injection (mainlining), cavitating septic thromboemboli, forceful exhalation of crack smoke into another individual's respiratory tract (shotgunning), or deep inhalation and Valsalva maneuvers while smoking marijuana. Emesis and coughing, both Valsalva maneuvers, can also cause spontaneous pneumothorax.

### Traumatic Pneumothorax

When a child has a traumatic pneumothorax, the physician must recognize that chest trauma is often an indicator of multisystem injury (eg, life-threatening head injury, abdominal injury). Trauma to the chest is classified as blunt or penetrating. The leading causes of blunt thoracic trauma are vehicle–pedestrian injuries and motor-vehicle crashes. Falls and child abuse are also causes of blunt traumatic pneumothorax. The leading causes of penetrating thoracic trauma are gunshot and stab wounds. In 1 report of children with blunt trauma, 38% had an associated pneumothorax, hemothorax, or both. In children with penetrating thoracic trauma, 64% had an associated pneumothorax, hemothorax, or both.

### Iatrogenic Pneumothorax

Iatrogenic pneumothoraces are caused by diagnostic or therapeutic interventions, including transthoracic-needle aspiration, central venous catheter insertion, thoracentesis, and barotrauma or volutrauma related to mechanical ventilation. Rates of pneumothorax caused by mechanical ventilation have fallen in all

age groups because of improved modes of mechanical ventilation with better patient synchrony and lower tidal-volume strategies that limit delivered airway pressure. Use of surfactant has also been credited with substantial decreases in pneumothorax rates for preterm neonates (30%–65%). The observed rate of iatrogenic pneumothorax in the hospitalized pediatric population was recently reported as 0.06 per 1000 discharges. Some reports note an incidence of iatrogenic pneumothorax that exceeds that of spontaneous pneumothorax.

### Neonatal Pneumothorax

The incidence of neonatal pneumothorax depends on gestational age, birth weight, and the presence of lung disease. Spontaneous pneumothorax is present in 1% to 2% of live births, and most are term infants. Of affected infants, about one-half have symptoms. A history of delivery-room resuscitation efforts or infant aspiration of meconium or blood often exists. Pneumothoraces are common in critically ill ventilated neonates, and the incidence increases with prematurity. Pneumothorax in an infant with the neonatal respiratory distress syndrome is associated with mortality rates exceeding 60% in some studies. Familial cases of spontaneous pneumothorax in neonates have also been described.

### PNEUMOMEDIASTINUM

Pneumomediastinum is uncommon in the pediatric population and is usually self-limited. Although no apparent consensus exists regarding classification of pneumomediastinum, the term *spontaneous pneumomediastinum* is used frequently in the medical literature and is applied to younger patients who have no obvious precipitating event. The incidence of spontaneous pneumomediastinum detected by screening symptomatic infants was 25 of 10,000 live births. The incidence of spontaneous pneumomediastinum in the noninfant pediatric population is not known. The most common etiology of spontaneous pneumomediastinum in pediatric patients is bronchospasm related to respiratory tract infection. Because healthy young people do not often have severe symptoms or physical examination findings, spontaneous pneumomediastinum may go undetected, and the actual incidence is thus difficult to ascertain.

Pneumomediastinum is seen in a variety of clinical circumstances; it is often associated with exaggerated Valsalva maneuvers during cough, emesis, hiccupping, heavy lifting, straining at stool, illicit drug inhalation, and sports activities. Pneumomediastinum has been noted in situations in which external pressure changes occur, such as scuba diving and air travel. Marked decreases in interstitial pressure such as that seen with hyperpnea from diabetic ketoacidosis can also cause pneumomediastinum. Asthma is a well-recognized risk factor. Pneumomediastinum is associated with barotrauma or volutrauma secondary to mechanical ventilation or manual resuscitative ventilation. The physician must consider the possibility of foreign body as a cause of pneumomediastinum, especially in children younger than 6 years. Spontaneous esophageal perforation (Boerhaave syndrome) and

mediastinitis must be considered in the differential diagnosis.

Pneumomediastinum can be secondary to trauma and has been reported in child abuse and other blunt thoracic trauma such as motor-vehicle crashes. Isolated facial trauma has also been reported as a cause. Tracheobronchial and esophageal rupture can also cause pneumomediastinum. Care must be taken to evaluate for penetrating injury because air can enter the mediastinum from penetrating neck or chest wall injury.

### EVALUATION OF PNEUMOTHORAX

#### History

Patients often note abrupt ipsilateral pleuritic chest pain with or without acute dyspnea. Pleuritic pain may be more prevalent in primary than in secondary spontaneous pneumothorax. Dyspnea is typically quite severe in patients with secondary spontaneous pneumothorax because they have decreased cardiopulmonary reserve at baseline. Symptoms associated with primary spontaneous pneumothorax often resolve within 24 hours, even if untreated. This feature contrasts with the progressive course of secondary spontaneous pneumothorax. Respiratory symptoms might be vague in young children, and parents may note sudden dyspnea and irritability.

#### Physical Examination

The physical examination findings in primary spontaneous pneumothorax are variable and depend on the pneumothorax size and patient age. A patient with a pneumothorax occupying less than 15% of the hemithorax may have a normal physical examination. Most commonly, vital signs demonstrate tachycardia and tachypnea. Hypoxemia caused by a small primary spontaneous pneumothorax is uncommon in older children because most will have adequate alveolar reserve to preserve oxygenation. However, smaller children are often hypoxemic. Because the underlying lung function is normal, hypercarbia does not typically develop in patients with primary spontaneous pneumothorax. In contrast, patients with secondary spontaneous pneumothorax often have hypoxemia and hypercarbia, and as the size of the pneumothorax increases, characteristic signs such as diminished or absent breath sounds, hyperresonance to percussion on the involved side, and chest asymmetry may be noted.

Neonates may have severe respiratory distress with marked tachypnea, grunting, retractions, and cyanosis. In infants with respiratory distress syndrome or other underlying lung disease, pneumothorax can be rapidly life-threatening. Such infants may demonstrate cardiorespiratory instability and progress to cardiac arrest. Detection of pneumothorax by physical examination in infants can be difficult because of the small thorax size; however, a shift of the apical heart impulse away from the side of the pneumothorax has been reported to be a reliable sign.

Iatrogenic pneumothorax should be suspected in any patient who becomes more dyspneic after a medical or surgical procedure known to be associated

**Figure 368-1** Pneumothorax. A white visceral pleural line is separated from the parietal pleura by radiolucent air. (Used with permission from Richard Wiggins, MD.)

with the development of a pneumothorax. Iatrogenic pneumothorax should also be suspected in any patient treated with positive pressure ventilation who experiences a sudden clinical deterioration or demonstrates an unexplained increase in peak and plateau pressures or decreased tidal volume.

No matter the pneumothorax classification, hypotension, profound hypoxemia, or tracheal deviation in the setting of diminished breath sounds heralds *tension* pneumothorax, which is life threatening and requires immediate attention. Intervention for tension pneumothorax should not be delayed for radiologic imaging to confirm the diagnosis.

### Laboratory Testing

Pneumothorax diagnosis is routinely made by chest radiograph, preferably with the patient in an upright position. The main radiologic feature of a pneumothorax is a white visceral pleural line, separated from the parietal pleura by an avascular collection of gas (Figure 368-1). In many instances, no pulmonary vessels are visible beyond the visceral pleural edge. In films in which the patient is upright, the accumulation of gas occurs primarily in an apicolateral location. In supine views, more pleural gas is needed for definitive diagnosis of a pneumothorax. The pleural gas accumulates in a subpulmonic location, outlining the anterior pleural reflection, the costophrenic sulcus (the so-called deep sulcus sign), and the anterolateral border of the mediastinum.

A computed tomography (CT) scan can detect pneumothoraces that do not appear on radiograph (occult pneumothoraces) but is often not practical in the initial workup. Portable ultrasound devices may

play a role in the future, but application of thoracic ultrasound for pneumothorax in children has yet to be established. In young infants, neonatal pneumothorax must be differentiated from congenital lobar emphysema, which can appear as an expanded radiolucent pulmonary segment. A CT scan may be required to make this differentiation, which is important because the treatment for congenital lobar emphysema is lobectomy. Aspiration or chest tube placement in a patient with congenital lobar emphysema is associated with substantial risk for mortality.

In trauma patients, the presence of a large pneumothorax with persistent air leak into the pleural space despite tube thoracostomy is an indication for fiberoptic bronchoscopy to assess the possibility of a bronchial tear. Physicians must also rule out traumatic rupture of the esophagus because the mortality rate approaches 100% if surgical treatment is not prompt.

## EVALUATION OF PNEUMOMEDIASTINUM

### History and Physical Findings

Patients with pneumomediastinum may complain of chest pain, cough, and dyspnea, as well as dysphonia, dysphagia, or neck pain. The examination will often reveal subcutaneous cervical emphysema with crepitance. Less commonly, Hamman sign (a mediastinal crunching sound synchronized with systole) may be heard.

### Laboratory Testing

Pneumomediastinum is recognized by air outlining mediastinal structures such as the thymus (sail sign) or the superior surface of the diaphragm (continuous-diaphragm sign). Pneumomediastinum is usually bilateral and does not move with decubitus positioning, which helps differentiate it from anteromedial pneumothorax (Figure 368-2). However, pneumothorax may also be present.

## MANAGEMENT OF PNEUMOTHORAX

### Primary Spontaneous Pneumothorax

#### Management of Small Primary Spontaneous Pneumothorax in Adolescents and Young Adults

Although guidelines for the management of spontaneous pneumothorax in adult patients have been published by both the British Thoracic Society and the American College of Chest Physicians, no similar guidelines exist for treatment of infants and small children. The British and American adult guidelines distinguish between small and large primary spontaneous pneumothorax in the recommended treatment pathways. Small pneumothoraces are defined as less than 15% to 20% of the chest volume.

These guidelines estimate loss of lung volume by the distance from the lung apex to the ipsilateral thoracic cupola at the parietal surface on a standard upright radiograph. This method is, however, a poor way of quantifying pneumothorax volume, usually underestimating it. The British Thoracic Society defines *small* as

**Figure 368-2** Pneumomediastinum. The mediastinal structures, usually invisible, are outlined, particularly the medial side of the descending aorta.

a rim less than 2 cm, whereas the American College of Chest Physicians define *small* as a rim less than 3 cm. This simple linear measurement is of little use for infants and small children but can be applied in adolescents and young adults. Another way to estimate the size of a pneumothorax is to realize that the volume of the lung approximates the ratio of the lung diameter to the hemithorax cubed. The physician can measure the ratio of length of the lung to the hemithorax at several rib levels and apply the following formula:

$$\text{Estimated size of pneumothorax (\%)} = (1 - L^3/H^3) \times 100,$$

where H = diameter of the hemithorax, and L = diameter of the *collapsed* lung (Figure 368-3).

Using this formula, a pneumothorax smaller than 15% would be considered small. If the pneumothorax size is small, and if the severity of acute symptoms is mild with unlabored breathing, and if room air saturations are greater than 90%, then supplemental oxygen and observation in the emergency department (ED) for 3 to 6 hours, followed by a repeat chest radiograph to exclude progression of the pneumothorax, is recommended for adolescents and young adults. Patients must have careful instructions to return for worsening shortness of breath and have a follow-up in 12 hours to 2 days with a planned chest radiograph to document improvement. Breathless patients should undergo intervention, regardless of pneumothorax size. All patients should be referred to a lung specialist for follow-up care because they have recurrent risk for spontaneous pneumothorax. Smoking is a risk factor for primary spontaneous pneumothorax recurrence, and smoking cessation should be encouraged. Supplemental oxygen is administered to all pneumothorax patients because it increases the pleural air reabsorption

**Figure 368-3** Measurements estimating volume of pneumothorax. (Reprinted from Shaw KS, Prasil P, Nguyen LT, Laberge J-M. *Pediatric spontaneous pneumothorax*. *Semin Pediatr Surg*. 2003;12[1]:55–61, with permission from Elsevier.)

rate 3- to 4-fold above the baseline of 1.25% per day and is recommended to hasten resolution. A 15% pneumothorax is expected to resolve in about 12 days without oxygen therapy.

### Management of Small Primary Spontaneous Pneumothorax in Children

Children with small primary spontaneous pneumothorax are typically admitted for observation. However, based on the adult guidelines, older children and adolescents with asymptomatic small primary spontaneous pneumothorax who have been observed in the ED for 3 to 6 hours can be discharged to home with close follow-up as recommended for adult patients. Any patient with breathlessness should be admitted and should undergo intervention to remove the air. Although simple needle aspiration has been advocated by experts in the United Kingdom, such is not standard practice in the United States.

### Management of Moderate to Large Primary Spontaneous Pneumothorax in Adolescents and Young Adults

The British Guidelines recommend simple aspiration as the first-line treatment for all symptomatic primary spontaneous pneumothoraces and for all with greater than 2 cm rim of air on chest radiograph (large); however, the US guidelines do not generally endorse attempts at simple aspiration over placement of a chest drain. Recent publications regarding primary spontaneous pneumothorax in adults show

that aspiration is successful in more than 50% of cases but is more likely to fail if the pneumothorax is larger than 40%. A randomized study of 50 adult participants showed that aspiration was immediately successful in 59% of adults compared with immediate resolution of the pneumothorax in 64% of patients treated with a chest drain. Of note, 48% of the patients who had simple aspiration were discharged from the ED compared with none of the patients treated with chest tube placement. Success at 1 week did not differ between groups (93% vs 85%), and recurrence of spontaneous pneumothorax within 1 year was also similar (26% vs 27%). A meta-analysis of 3 randomized studies showed significantly shorter length of hospital stay with simple aspiration and equivalent success at 1 week compared with chest tube drainage. No difference in recurrence of pneumothorax was noted for 1 year after the initial spontaneous pneumothorax between treatment groups.

In the British Guidelines, patients who have successful aspiration of a primary pneumothorax may be observed in the ED for similar follow-up. The American College of Chest Physicians recommends placement of a chest drain for symptomatic or any large (>3 cm rim) primary spontaneous pneumothorax. Patients are then managed with either a Heimlich valve (one-way valve) or a chest tube to water seal or suction.

### **Management of Large Primary Spontaneous Pneumothorax in Children**

Simple aspiration versus chest tube placement for children with large pneumothorax is based on experience of the treating physician. However, published pediatric series suggest that hospital admission with placement of a pleural catheter or chest tube is usual practice.

### **Spontaneous Secondary Pneumothorax in Young Adults and Children**

Guidelines recommend hospital admission for patients with spontaneous secondary pneumothorax for treatment of the underlying condition and symptomatic treatment of the pneumothorax, if needed. Small pneumothoraces can be treated with oxygen therapy and observed, whereas large pneumothoraces are drained either by aspiration or by chest tube placement.

### **Traumatic Pneumothorax**

If a tension pneumothorax is suspected, then emergency needle aspiration of the second intercostal space in the midclavicular line is required. If the patient improves with needle aspiration, then a chest drain should immediately be placed on that side. However, a substantial number of pneumothoraces are not seen on initial chest radiographs but are found on subsequent imaging (CT or ultrasound) of the chest. Placement of a larger-caliber chest drain for symptomatic or large pneumothorax among trauma victims is customary treatment because many patients require positive pressure ventilation and may have an accompanying hemothorax. Small

asymptomatic pneumothorax may be observed if the patient is not receiving positive pressure and radiographic evaluation does not reveal chest multitrauma.

### **Iatrogenic Pneumothorax**

Treatment of iatrogenic pneumothorax should be tailored to the patient's clinical circumstance. Patients receiving positive pressure ventilation are at risk for extension of the pneumothorax and generally require chest tube placement. Patients who are not on mechanical support who have a small pneumothorax and limited symptoms can receive supportive care with close observation.

### **Chest Tube Insertion and Management**

#### **Planning**

Before inserting a chest tube, a predrainage risk assessment is appropriate. Risk for hemorrhage should be corrected when possible; however, routine platelet count and bleeding times are recommended only for patients with known risk factors. When possible, the physician should obtain informed consent and provide sedation with standard monitoring. Risks include bleeding, infection, failure of pneumothorax resolution, laceration of the lung, and extrathoracic placement with potential injury of abdominal organs. In 1 report, 3% of tubes were placed in an extrathoracic position, and 6% were placed in the lung parenchyma.

#### **Positioning**

The preferred position for chest drain insertion is supine with the ipsilateral arm above the patient's head to expose the axilla. Alternative positions are for the patient to sit upright leaning over an adjacent table with a pillow or in a lateral decubitus position. The triangle in Figure 368-4 illustrates the safe area that is bordered by the lateral margin of pectoralis major muscle, the anterior margin of the latissimus dorsi muscle, the line superior to the horizontal level

**Figure 368-4** Diagram to illustrate the safe triangle.

of the nipple, and an apex below the axilla. This supine position minimizes risk to underlying structures such as the internal mammary arteries, breast tissue, and solid organs. A more posterior position is chosen if the pneumothorax is loculated and posterior. However, loculated collections are most safely approached under fluoroscopic guidance. Although a more posterior position is safe, the chest tube is uncomfortable for the patient to lie on after insertion and is at risk for kinking. The second intercostal space in the midclavicular line may be chosen for apical pneumothorax; however, this position is uncomfortable and may leave a visible scar. A survey of house officers showed that about one-half did not know the recommended anatomic landmarks for safe chest tube insertion.

### Thoracostomy Tube Size Selection

Smaller tubes are recommended for aspirating air and are more comfortable than larger tubes, which are recommended for draining blood or a large air leak. Age-based sizes for thoracostomy tubes recommended for trauma victims by the American Heart Association are shown in Table 368-1. These tubes are relatively large based on the patient size and are intended to drain blood if needed. The Adult Guidelines for pneumothorax management recommend relatively smaller tubes for draining air. The British Guidelines recommend a 10- to 14-French tube for the management of pneumothorax in adults, whereas the American College of Chest Physicians recommends initial management with a 16- to 22-French tube in patients not at risk for large air leaks. Roberts and colleagues reported use of 7- and 8.5-French percutaneous pigtail catheters (polyurethane) in children, with resolution of pneumothorax in 75% of cases. In that study, the pigtail catheters drained serous fluid well (96% success) but were less effective for draining blood (81%) and ineffective for draining pus (0%). The catheters are much more pliant and can be kinked by the chest wall in obese patients; the tubing connection also can be kinked.

### Insertion Techniques

Small-bore chest tubes are usually inserted with the aid of a needle and guidewire using a modified Seldinger technique. Blunt dissection is not needed because a dilator is used. Blunt dissection of the subcutaneous tissue and muscle into the pleural cavity is performed for insertion of medium and large chest drains. A finger-sized opening allows exploration to ensure that no underlying organs will be damaged by

tube insertion; creation of the track prevents excessive force. Once the tube is past the chest wall, it is directed apically to drain air and basally to drain fluid. The chest tube is then sutured in place. If an incision has been made, then 1 stitch is placed to assist with wound closure after tube removal, and 1 stitch is placed to secure the drain. A chest radiograph is obtained after insertion to check placement and resolution of the pneumothorax.

### Management of Chest Drain

The chest tube is connected to a closed system with a water seal device. If the lung fails to expand quickly, then continuous suction delivered through a measured column of water is applied and remains until the lung has completely re-expanded. The closed system allows detection of air bubbles through the water chamber, suggesting continued visceral pleural air leak. However, an air leak may be caused by a leak in the system; the chest tube air holes are outside the chest, or the chest tubing connections are not airtight.

The chest tube should remain in place as long as persistent air leak is present. Surgical referral is recommended if air leak persists for longer than 4 to 7 days in patients without preexisting lung disease, and earlier referral is recommended if the lung fails to expand or in patients with a large air leak and underlying lung disease. Chest tubes are removed in a staged manner after a pneumothorax is resolved. Suction is discontinued, and the chest tube is placed on water seal. Opinions differ regarding the appropriate length of time for a water seal trial, ranging from 3 to 24 hours. After a trial on water seal, a chest radiograph is obtained to rule out recurrence. The chest tube may then be removed. Clamping of a chest tube should never be done unless the physician is expert in chest tube management and the patient has constant nursing supervision.

### Risk for Recurrence

Children with primary spontaneous pneumothorax have a 17% to 54% risk for recurrence, with a greatest risk for recurrence within 1 year. Some experts recommend CT imaging to detect pleural blebs after initial pneumothorax to help determine risk for recurrence. However, at this point, surgical treatment is generally limited to children with recurrent pneumothorax. Surgery usually involves repair of the air leak and adherence of the visceral pleura to the parietal pleura (pleurodesis). Surgical approach through a mini-thoracotomy or video-assisted thoracoscopic surgery (VATS) is based on surgeon's preference; however, VATS is associated with less postoperative pain and shorter hospital length of stay.

**Table 368-1** Age-Based Sizes for Thoracostomy Tubes

AGE (WEIGHT IN KG)	CHEST TUBE SIZE (FRENCH)
Newborns (2-5 kg)	8-12
<1 yr (5-11 kg)	14-20
Children 1-8 yr (12-30 kg)	20-28
Children >8 yr (>30 kg)	29-36

## MANAGEMENT OF PNEUMOMEDIASTINUM

Initial therapy for pneumomediastinum is directed at the underlying disease process. Because mediastinal air decompresses into the cervical fascia and rarely causes tamponade, observation is standard management. Efforts to lower intrathoracic pressures or tidal volume among patients receiving mechanical ventilation may decrease continued air

leakage. If signs of tamponade occur, then placement of a mediastinal tube using echocardiographic guidance should be done by a specialist with skills in this procedure. Because of the high prevalence of asthma-related pneumomediastinum, children for whom the underlying cause of pneumomediastinum is unknown should undergo diagnostic pulmonary function tests after the acute episode.

### WHEN TO REFER

- Infants and children with primary or secondary spontaneous pneumothorax or spontaneous pneumomediastinum should be referred to either a hospital or an ED for evaluation and management. All children with spontaneous pneumothorax should be referred to a lung specialist for follow-up because of the risk for recurrent pneumothorax.
- Infants and children with traumatic pneumothorax should be referred to a trauma center for evaluation and management.
- Infants and children with iatrogenic pneumothorax should be cared for by physicians with expertise in chest drain insertion and management.
- Infants and children with pneumomediastinum and signs of cardiac tamponade should be evaluated by a cardiologist or surgeon able to place a mediastinal drain.

### WHEN TO ADMIT

- Children with asymptomatic small primary spontaneous pneumothorax who have been observed for 6 hours in the ED and who have reliable transportation and social circumstances can be considered for discharge from the ED with follow-up within 24 hours in the ED.
- Children with symptomatic pneumothorax of any size should be admitted to a hospital for observation or management.
- All infants with pneumomediastinum or pneumothorax should be admitted to a hospital.
- Any trauma victim with pneumothorax or pneumomediastinum should be admitted to a trauma center for evaluation and management.

## Chapter 369 POISONING

Jeffrey S. Fine, MD

Injuries are a leading cause of pediatric morbidity and mortality, and poisoning is one important mechanism of injury. As a result, physicians who provide primary care to children have been at the forefront in promoting the field of medical toxicology, particularly in the area of poison prevention. This chapter reviews the epidemiologic considerations of pediatric poisoning and provides more specific information on some important poisonings.

### EPIDEMIOLOGIC FEATURES

The ingestion of potentially toxic substances is a common pediatric problem. More than 2 million ingestions are reported each year to the American Association of Poison Control Centers (AAPCC); approximately 65% are exposures that involve children and adolescents up to 19 years of age. Children younger than 6 years account for approximately 80% of these childhood and teenage exposures and, as a result, for more than 50% of all reported childhood, adolescent, and adult exposures. Males account for approximately 55% of childhood exposures and 45% of the adolescent reports.

Childhood exposures most frequently occur in children between 1 and 3 years of age. In young children, ingestions result from the natural curiosity, increasing mobility and dexterity, and oral exploration typically displayed by toddlers. Although a young child may find a pill and purposefully put it in his or her mouth, the resulting toxicity, if it occurs, is “unintentional,” and the typical exploratory childhood ingestion is generally referred to as an unintentional exposure.

Several characteristics differentiate typical childhood exposures from adolescent and adult exposures: they are unintentional; only one agent is involved; the agents are frequently nontoxic; the amount ingested is small; and toddlers are brought in for evaluation soon after the ingestion is discovered.

Certain behavioral characteristics increase the risk for ingestion, such as hyperactivity, impulsive risk-taking behavior, rebelliousness, and negativistic attitude. In addition, social isolation, poor parenting skills, and maternal depression have been identified as family variables that predispose young children to unintentional poisonings. Unintentional exposures occur at times of family disorganization, with deviations from normal routines (eg, household moving, spring cleaning, vacation, holidays) and during times of family stress (eg, sickness, death, divorce). Repeat exposures may occur in as many as 10% to 40% of childhood poisoning victims.

Most childhood exposures occur in the child's own home. One common site of exposure in the home is the kitchen, where cleaning and polishing products are often stored underneath the sink or in easily accessible lower cabinet shelves. Improper storage of solvents and cleaning agents in drinking glasses, cups,

and beverage bottles contributes to the risk for unintentional exposures. Medications are sometimes stored in the refrigerator or left out on the kitchen table. In the bedroom, medications are left out on the dresser or on the bedside table. Medications and cosmetics are typically kept in the bathroom, another common site for unintentional exposures. The grandparents' home is another setting where unintentional exposures may occur. Grandparents often have cardiovascular or psychotropic medications at home and may not be as vigilant as parents in "child-proofing" their home. Grandparents' medications may not be in child-resistant containers.

Poisoning is unusual in children younger than 6 months. It may result from a medication error, intentional administration of a medication by a parent or sibling, or passive exposure to a psychoactive substance—for example, exposure to the smoke of crack cocaine or to methamphetamine being manufactured in a clandestine home laboratory. Child abuse and neglect should be part of the differential diagnosis of all cases of childhood poisoning, particularly when

the child is younger than 1 year. Children who ingest poisons may also be at risk for other types of injuries.

Unintentional ingestion is unusual after age 5 years. For school-aged children, poisoning may be a reflection of intrafamilial stress or suicidal intent. For older children and adolescents, xenobiotic exposure is usually intentional; the resulting toxicity may be unintentional. These exposures may be the result of a suicide attempt or gesture or the result of the recreational use of psychoactive substances. Adolescents are also at risk for repeat exposures.

Table 369-1 lists the AAPCC categories of agents to which children and adolescents are frequently exposed. Most pediatric exposures are to common plants and products found around the house and to pharmaceutical products. Pharmaceutical agents account for most fatalities. Table 369-2 lists the categories of agents responsible for poisoning fatalities. A comparison with Table 369-1 demonstrates that most exposures do not cause significant toxicity. Most childhood poisoning fatalities are caused by analgesic agents, carbon monoxide, hydrocarbons, cleaning agents, and cough and cold preparations. In contrast, most adolescent fatalities are caused by analgesic agents, drugs of abuse, and psychiatric medications. Childhood hydrocarbon deaths are

related to unintentional exposures with aspiration leading to acute lung injury, whereas adolescent hydrocarbon fatalities are typically related to intentional inhalant abuse with unintentional asphyxiation.

Poison-related mortality is low overall; poisoning deaths represent 3% of annual childhood and adolescent deaths from unintentional injury. For children younger than 6 years, the AAPCC reported an average of 24 deaths per year from 1983 to 2013.

These deaths represent only 4% of the poisoning fatalities for all age groups and a 94% decrease from a high of 456 in 1959. Factors contributing to this decline include pediatric anticipatory guidance, preventive measures that include child-resistant closures and unit-dose packaging, and improved medical care.

Childhood exposures have changed in recent years. Aspirin overdoses, once a leading cause of death in children, are now rare. This change may be related to packaging changes and to the decreased antipyretic and analgesic use of aspirin at home because of its previous association with Reye syndrome. Some agents, such as kerosene or lye, which remain a significant risk in other countries, are rare causes of poison-related mortality in the United States.

Iron poisoning was also formerly a leading cause of poison-related mortality; but now, childhood iron poisoning is rare. This reduction may be the result of changes in packaging. In 1997 the US Food and Drug Administration (FDA) issued a regulation to package products with 30 mg or more of elemental iron per tablet in unit-dose packages such as blister packs. In 2003 this rule was overturned when it was legally determined that the FDA did not have the statutory authority to regulate a medication for the purpose of poison prevention.

## PREVENTION

Every child is at risk for a potentially toxic exposure; thus effective prevention strategies are directed toward the environment of all children and require parental cooperation. Primary care physicians must educate parents and caregivers in the importance of safe storage practices for household products and prescription medications, as well as the use of child-resistant closures, the only preventive measure of proven efficacy. The American Academy of Pediatrics (AAP) recommends anticipatory guidance about poisoning prevention beginning with the 6-month well-child visit. Educational materials are available from the AAP as part of the Injury Prevention Program. All parents should be given the telephone number of Poison Help (1-800-222-1222), which connects callers to a regional poison control center, and should be advised to keep the number posted by the telephone and programmed into mobile phones for immediate use if necessary.

With respect to prevention, a caretaker's primary responsibilities include selecting appropriate products for storage within the home, selecting an appropriate place to store these products, and practicing prompt disposal of old, unused, and unnecessary medications and potentially toxic materials. Toxic substances (medications, psychoactive substances, alcohol, household chemicals, and products) must be inaccessible to children and

stored in locked cabinets or boxes. These agents should be kept in their original containers so that they are not mistaken for food, beverages, or nontoxic products. If toxic substances are no longer being used, then they should be safely discarded according to the pharmaceutical manufacturer's recommendations or returned to the pharmacy where "take-back" programs are available. Guidance regarding the appropriate disposal of chemicals and other potentially hazardous household products is available from the US Environmental Protection Agency (EPA) and various local and state governmental agencies.

Parents should be advised to exercise particular care with agents that can be fatal to a toddler in small doses (see Box 369-1). They should also be cautioned about a few agents to which children are infrequently exposed but which cause severe toxicity, such as acetonitrile (artificial fingernail remover), ammonium fluoride (wheel cleaner or rust-removal agent), and selenious acid (gun-bluing compound).

Preventing errors in the administration of therapeutic medications is another area where caregivers play an important role. It is critical to ensure that the right patient gets the right medication in the right dose at the right time by the right route. It is recommended that medications be prescribed and dispensed in metric doses only (eg, mg or mL) and that patient-specific dose labeling be indicated on clearly labeled liquid medication devices at the time medications are dispensed. With regard to the home administration of prescribed or over-the-counter liquid medications, it is important to use metric-only dosing devices such as a graduated spoon or cup; other devices such as teaspoons or droppers are not accurate and can lead to unintentional underdose or overdose resulting from measuring errors.

### BOX 369-1 Agents With Significant Toxicity in Toddlers After a Small Dose

- Antihistamines
- Benzocaine
- $\beta$ -Adrenergic antagonists (sustained release)
- Calcium channel antagonists (sustained release)
- Camphor
- Clonidine
- Diphenoxylate-atropine (Lomotil)
- Ethylene glycol
- Methanol
- Methylsalicylate (oil of wintergreen)
- Opioids (methadone, codeine, oxycodone)
- Phenothiazine
- Quinine, chloroquine
- Sulfonylurea antidiabetic agents
- Theophylline
- Tricyclic antidepressants

## PRINCIPLES OF MANAGEMENT

### General Considerations

Primary care physicians should be familiar with the signs, symptoms, and management of common acute ingestions. Recent toxicology textbooks are an important part of an office library. Micromedex, a commercial poison information software package, is available in many emergency treatment facilities and in many medical libraries. Access to much of this material is available online.

Primary care physicians should be familiar with community resources that can provide information or practical help with acute poisonings. Pharmacists can provide information about medications when the name of the medication or the amount dispensed does not appear on the label. Manufacturers can help identify the chemicals in a commercial product. Local or regional emergency care facilities should be identified that can accept patients for urgent evaluation and care.

Poison control centers provide comprehensive information on poison management and other toxic exposures and can usually help organize a referral to an appropriate treatment facility. Guidance for management of acute poisonings, prevention of poisonings, and assessment of poison hazards is available 24 hours a day from the Poison Help Line of the AAPCC at 1-800-222-1222. In addition to guidance in managing acute poisonings, the Poison Help Line can provide information regarding questions such as how to clean up a broken CFL bulb or whether to worry about chemicals in plastic bottles. A list of regional poison centers can be found at the Web site of the AAPCC ([www.aapcc.org](http://www.aapcc.org)).

### Telephone Calls

Telephone triage is an important first step in managing potentially toxic exposures. Many exposures can be managed over the telephone, although home therapy of serious poisonings is limited. The physician should determine the name and type of agent, the quantity involved, the weight of the child, and the presence or absence of symptoms (see Box 369-2). The relative risk for toxicity can then be estimated. Alternatively, symptoms alone may indicate toxicity, despite the fact that, by history, neither the agent nor the dose would have predicted it. In the case of non-toxic exposures, reassurance is appropriate.

#### **BOX 369-2** Important Historical Questions Regarding a Possible Toxic Exposure

- What was the substance?
- What was the specific name of the product?
- What was the formulation of the substance?
- How much of the substance was involved?
- How much does the child weigh?

Prompt decontamination may reduce subsequent symptoms and the need for further treatment. Skin and eyes may be washed in the home or office, if appropriate.

When the history of the exposure or the reported signs and symptoms suggest an acute toxicity, the patient should be expeditiously transferred to an emergency care facility, ideally one with pediatric and toxicologic expertise and experience.

Although many calls can be initially managed by primary care practitioners, especially in the case of nontoxic exposures, all calls regarding potentially toxic exposures should be referred to trained poison information specialists at local and regional poison control centers.

Poisoning and injury prevention should be discussed with parents within a few days of a poison exposure call. Experience suggests that addressing prevention at the time of the initial call is less effective than doing so later. The recent exposure may focus the mind of the parents, providing a valuable opportunity to impart advice on poison prevention.

### Approach to the Symptomatic Patient

When no specific history of a toxic exposure can be found, the diagnosis of poisoning can be challenging. The signs and symptoms of poisoning can mimic those of many acute illnesses; therefore the possibility of toxic exposure should be considered in the differential diagnosis. The rapid onset of central nervous system (CNS), gastrointestinal (GI), or respiratory symptoms should alert the physician to ask about possible exposures to medications, gases, or fumes (eg, carbon monoxide) or to other potentially harmful substances around the home. The physician should always consider the possibility of poisoning when faced with a puzzling situation in which the diagnosis is unclear. Any patient with a possible or confirmed exposure to a toxic substance should be managed in consultation with poison specialists available through a local or regional poison control center and additionally, for emergency and admitted patients, hospital-based toxicology consultants when available.

Some xenobiotics such as opioids or anticholinergic agents produce a typical constellation of signs and symptoms known as a *toxidrome*, or toxic syndrome (see Box 369-3). When present, these toxidromes may suggest a likely agent.

This chapter focuses on the medical management of acute poisonings. For many patients, this phase of care represents only the beginning of a complete multidisciplinary evaluation. A patient with unresolved toxicity will generally require admission to an observation or inpatient unit for ongoing medical care. After toxic manifestations are resolved or the risk for toxic effects is past, many patients require consultation with mental health services for an evaluation of the need for psychiatric admission.

## THERAPEUTIC MODALITIES

The important principles of the management of acute poisonings are (1) resuscitation—attention to the ABCs (airway, breathing, and circulation) and D (disability—altered mental status and seizures), (2) decontamination,

(3) administration of specific antidotes, (4) enhanced elimination, and (5) supportive care. Although management will typically follow this sequence, in certain cases, priorities will differ. For example, in a chemical terrorism event, decontamination may need to precede any medical intervention, even resuscitation. After an opioid overdose with respiratory arrest, administration of naloxone, an opioid antidote, is part of resuscitation.

**Resuscitation**

Some poisons cause toxicity that requires immediate attention. Such effects include airway obstruction, difficulty breathing, dysrhythmias, hypotension, and seizures. Specific details of the resuscitation of the poisoned patient are beyond the scope of this chapter; however, resuscitation generally proceeds according to the recommendations of the American Heart Association within the Pediatric Advanced Life Support (PALS) and the Advanced Cardiac Life Support (ACLS) programs.

Patients with airway obstruction or respiratory failure require urgent airway management and may require assisted ventilation or endotracheal intubation. Patients with respiratory depression should receive an empirical trial of naloxone. This agent is both diagnostic and therapeutic for opioid intoxication and may preclude the need for intubation.

An escalating dosing scheme allows administration of sufficient naloxone to reverse respiratory depression without precipitating withdrawal in a person chronically exposed to opioids (see Table 369-3). For patients with a prolonged opioid effect that outlasts the effect of a single reversing dose, naloxone can be administered as a continuous infusion. Naloxone-induced withdrawal in an opioid-dependent patient can cause profound hypertension and tachycardia that may be associated with cardiac dysrhythmias and pulmonary edema. Although naloxone administration may precipitate seizures as part of the withdrawal

syndrome in newborns born to opioid-dependent mothers, seizures are not a typical part of the withdrawal syndrome in patients outside of the newborn period who are chronically exposed to opioids.

The clinical toxicity of clonidine (a presynaptic  $\alpha_2$  agonist) with altered mental status and respiratory depression resemble the opioid toxidrome. Some cases of respiratory depression associated with clonidine poisoning have also responded to treatment with naloxone; however, clonidine and certain opioids may require higher doses of naloxone before a treatment effect is seen. A failure to respond to naloxone does not rule out clonidine intoxication.

Hypotension should be treated with a saline bolus and infusion. Hypotension unresponsive to fluid alone may require the use of a vasopressor. Although the use of dopamine is common, it acts indirectly by releasing epinephrine and norepinephrine, which are stored within the nerve terminal. When these stores are depleted, a direct-acting agent such as norepinephrine may be useful.

Patients experiencing cardiovascular toxicity from certain agents such as clonidine, beta blockers (BBs), calcium channel blockers (CCBs), tricyclic antidepressant agents, cocaine, and type 1 antidysrhythmic agents (eg, quinidine) may benefit from antidotal therapy (see Table 369-3).

Many xenobiotics cause altered mental status, and several antidotes may be appropriately administered during the resuscitation phase. Although the primary reason for administering naloxone is to reverse respiratory depression, patients who have coma related to opioid intoxication may wake up after the administration of naloxone.

All patients with an altered mental status should be evaluated for hypoglycemia at the bedside by a glucose oxidase test strip. Hypoglycemia should be promptly treated with dextrose (see Table 369-3). However, there is little risk associated with empirically administering a large dose of glucose to a child or adolescent with

Table 369-3

Antidote Table<sup>a</sup>

SUBSTANCE	ANTIDOTE	DOSE	COMMENTS
Acetaminophen	N-acetylcysteine	IV: 150 mg/kg over 1 hr, then 50 mg/kg over 4 hr, then 100 mg/kg over 16 hr. (Maximal weight for calculation: 100 kg)	AE: vomiting (PO); anaphylactoid reaction (IV). IV protocol requires large volumes of free water, which may cause hyponatremia and seizures in children.
Anticholinergic agents (eg, atropine)	Physostigmine	P: 0.02 mg/kg (max: 0.5 mg) IV slowly over 5 min A: 1–2 mg IV slowly over 5 min	May repeat dose after 10–15 min AE: cholinergic symptoms occur with excessive dosing.
Benzodiazepines	Flumazenil	P: 0.01 mg/kg IV slowly every min (max: 0.2 mg/dose, max: 1 mg total dose) A: 0.1–0.2 mg IV slowly every min (max: 1 mg)	Titrate to effect or maximal dose. May not reverse respiratory depression. If positive response is of short duration, may be administered as a continuous infusion AE: withdrawal symptoms in dependent or chronic use; seizures or dysrhythmias in cyclic antidepressant overdose
β-Adrenergic antagonists (BB)	Glucagon	P: 0.05 mg/kg IV over 1–2 minutes A: 0.05 mg/kg IV over 1–2 minutes	If positive response is of short duration, may be administered as a continuous infusion AE: vomiting, hyperglycemia, hypocalcemia
	Insulin and dextrose	Insulin 0.5 U/kg/hr IV with dextrose 1 g/kg/hr	AE: hypoglycemia or hyperglycemia, hypokalemia
	Intralipid 20% emulsion <sup>48</sup>	1.5 mL/kg bolus; 0.25 mL/kg/min for 30–60 min	Bolus can be repeated 1–2 times for persistent asystole. Infusion rate can be increased if the BP declines.
Carbon monoxide	Oxygen (100%)	100% oxygen by nonrebreather	Treat until normal CO level or until hyperbaric oxygen initiated.
	Oxygen (hyperbaric)	100% oxygen at 2–3 atmosphere for 20 min	AE: pneumothorax, perforated tympanic membrane.
Calcium channel blockers	Calcium chloride (10%)	P: 20 mg/kg (0.2 mL/kg) IV slowly, via central line A: 1–2 g (10–20 mL) IV slowly	May use glucagon, insulin and dextrose, and intralipid rescue as adjunctive treatment in CCB as in BB toxicity AE: hypercalcemia, phlebitis, nausea, vomiting, flushing, confusion, angina
	Calcium gluconate (10%)	P: 60 mg/kg (0.6 mL/kg) A: 3–6 g (30–60 mL) IV	
	Insulin and dextrose	Insulin 0.5 U/kg/hr IV with dextrose 1 g/kg/hr	
	Intralipid 20% emulsion <sup>48</sup>	1.5 mL/kg bolus; 0.25 mL/kg/min for 30–60 min	
Cyanide	Hydroxocobalamin	P: 70 mg/kg IV (max: 5 g IV) A: 5 g IV	May repeat x 1
Digoxin	Digoxin-specific antibody fragments	For known ingested dose: number of vials = mg ingested × 1.5 For known SDC (ng/mL): number of vials = SDC × weight (kg)/100 For unknown SDC or dose acute overdose: 10–20 vials For chronic overdose: P: 2 vials; A: 5 vials	Each 40-mg vial binds 0.6 mg digoxin. AE: hypokalemia, worsening CHF
Ethylene glycol and methanol	Fomepizole (4-methylpyrazole)	15 mg/kg over 30 min IV, then 10 mg/kg/dose every 12 hr × 4 doses, then 15 mg/kg/dose every 12 hr	Continue therapy until serum methanol or ethylene glycol level <20 mg/dL. Increase dose during dialysis. AE: headache, nausea, dizziness, bradycardia, eosinophilia, transient increase of liver enzyme levels
Heparin	Protamine sulfate	Use 1 mg protamine for every 100 units of heparin to be neutralized.	AE: hypotension, bradycardia, hemorrhage. Use with caution with known fish allergy.

**Table 369-3** Antidote Table<sup>a</sup>—cont'd

SUBSTANCE	ANTIDOTE	DOSE	COMMENTS
Iron	Deferoxamine	5–15 mg/kg/hr IV (max: 6 g/24 hr)	Titrate dose slowly to avoid hypotension. Continue therapy until <i>vin rose</i> urine color clears, symptoms clinically resolve, or maximal dose attained. Deferoxamine challenge no longer suggested AE: flushing, hypotension, acute respiratory distress syndrome
Isoniazid (INH)	Pyridoxine (vitamin B <sub>6</sub> )	Known INH dose: 1 g per g of INH ingested IV slowly Unknown INH dose: 5 g IV over 10 min	Administer 1 g every 2–3 min. AE: CNS toxicity—headache, seizure, peripheral neurotoxicity
Lead	Succimer (DMSA)	10 mg/kg/dose PO every 8 hr × 5 days, then 10 mg/kg/dose twice daily × 14 days	AE: rash, neutropenia, increased LFTs, GI upset
	Dimercaprol (BAL)	75 mg/m <sup>2</sup> /dose IM every 4 hr (max: 450 mg/m <sup>2</sup> /dose/24 hr)	Pretreatment with diphenhydramine suggested. Contraindicated with peanut allergy, hepatic insufficiency. AE: G6PD hemolytic crisis, nausea, vomiting, histamine release
	CaNa <sub>2</sub> EDTA	1–1.5 g/m <sup>2</sup> /day continuous IV infusion × 5 days	In cases of encephalopathy, administer after dimercaprol to prevent increased CNS lead levels. AE: phlebitis
Methanol Methemoglobinemia	See Ethylene glycol Methylene blue (1%)	1–2 mg/kg IV over 5 min	Repeat doses as needed. AE: dyspnea, chest pain, and hemolysis
Opioids	Naloxone	Full reversalN: 0.1 mg/kg IV/IM IV/IM/IO/SCP: <5 yr old or <20 kg: 0.1 mg/kg IV/IM/IO/SC/ET≥5 yr old or ≥20 kg: 2 mg IV/IM/IO/SC/ETPartial reversal: A: 0.04–0.08 mg IV/IM/IO/SC/ET Continuous infusion:P: 0.0025–0.01 mg/kg/hr	ET route not recommended for newborns. Do not administer naloxone to a newborn whose mother is suspected of chronic opioid use because of the risk for seizures with acute withdrawal. In general, full reversal is indicated for an opioid-naïve patient with an unintended acute opioid exposure. Higher doses may be required for certain agents or for high-dose exposures. Partial reversal at approximately 1/10 the full reversal dose is indicated for patients with chronic opioid exposure and acute respiratory depression that may be related to opioid exposure. The goal in this type of patient is to reverse respiratory depression without inducing acute withdrawal. For infants and children, 1–15 mcg/kg may reverse the respiratory depression associated with therapeutic opioid use. Doses may be repeated as needed to maintain opiate reversal. If a positive response is of short duration, repeat bolus dosing or continuous infusion may be required. Patients should be observed continuously for recurrence of respiratory depression and other opioid effects for at least 2 hr after the last dose of naloxone. AE: opioid withdrawal (piloerection, agitation, vomiting hypertension, tachycardia), pulmonary edema, seizures (in neonate)

**Table 369-3** Antidote Table<sup>a</sup>—cont'd

SUBSTANCE	ANTIDOTE	DOSE	COMMENTS
Cholinergic agents (eg, malathion)	Atropine	P: 0.02 mg/kg IV initial dose (min: 0.1 mg) A: 0.5–1 mg IV initial dose	Double dose every 3–5 min. Titrate to reduced bronchorrhea or improved oxygen saturation. May require total doses 5 or 10 times the initial dose or higher. AE: anticholinergic toxicity
	Pralidoxime	P: 25–50 mg/kg over 30–60 min, then 20 mg/kg/hr A: 1–2 g IV over 15–30 min, then 0.5 g/hr	Pralidoxime should be administered in addition to atropine. Continue therapy for 24–72 hr.
Oral antidiabetic agents	Octreotide	P: 1–2 mcg/kg SC/IV every 6–12 hr A: 50–100 mcg SC/IV, then 50 mcg every 12 hr	Continue therapy until euglycemic. May require several days of therapy. AE: bradycardia, dysrhythmias, GI upset, hyperglycemia
	Dextrose	Neonatal: 0.2 g/kg IV (use D <sub>10</sub> W, 2 mL/kg) P: 0.5–1 g/kg IV (use D <sub>25</sub> W, 2–4 mL/kg) A: 25 to 50 g IV (use D <sub>50</sub> W)	AE: hyperglycemia, extravasation may cause local tissue reaction. Patients able to release insulin in response to glucose administration may develop recurrent hypoglycemia.
Tricyclic antidepressants	Sodium bicarbonate	1–2 mEq/kg IV bolus, then titrate to pH ~7.5 with additional doses or with continuous infusion	AE: volume overload, hypernatremia, metabolic alkalosis
Warfarin	Vitamin K	P: 1–5 mg SC/IM/IV/PO, every 6–8 hr PRN A: 10 mg SC/IM/IV/PO, every 6–8 hr PRN	Much larger doses may be required. Continue therapy until INR within normal limits.

<sup>a</sup>Pediatric (P) and adult (A) doses are the same unless specifically noted.

A, Adult; AE, adverse effects; BB,  $\beta$ -adrenergic blocker; CCB, calcium channel blocker; CHF, congestive heart failure; CNS, central nervous system; CO, carbon monoxide; D<sub>10</sub>W, 10% dextrose and water; ET, endotracheally; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; Hb, hemoglobin; IM, intramuscular; INR, international normalized ratio of prothrombin time; IO, intraocular; IV, intravenous; LFT, liver function tests; max, maximum; min, minimum; N, neonate; P, pediatric; PO, oral; PRN, as needed; SC, subcutaneous; SDC, serum digoxin concentration.

altered mental status, and many physicians opt to administer glucose without specific bedside testing. If a patient is intoxicated with an antidiabetic agent that has a long half-life (eg, glipizide), then a continuous intravenous dextrose infusion or the administration of octreotide may be required (see Table 369-3).

The empirical use of the benzodiazepine antagonist flumazenil to treat CNS depression after an overdose of an unknown agent is controversial. Flumazenil administration is appropriate in the setting of a known acute benzodiazepine exposure associated with significant CNS or respiratory depression. Flumazenil may precipitate withdrawal seizures in the patient with benzodiazepine dependence, and it may induce dysrhythmias or seizures in patients exposed to tricyclic antidepressant agents. If the duration of the antagonistic effect of flumazenil is shorter than that of the xenobiotic, then repeat doses or a continuous intravenous infusion of flumazenil may be required (see Table 369-3).

Intoxication or poisoning is only one cause of altered mental status. Other important causes are trauma and CNS infection. Trauma is especially important to consider because intoxication is common before trauma. When the cause of altered mental status is unclear, cranial computed tomographic imaging should be

considered. In addition, a lumbar puncture should also be considered in cases of altered mental status, especially in the presence of fever.

Many xenobiotics cause seizures and require urgent intervention. Benzodiazepines are the preferred agents for the initial treatment of most xenobiotic-induced seizures. However, seizures related to isoniazid or the *Gyromitra* species of mushrooms (false morel) should be treated with pyridoxine (vitamin B<sub>6</sub>); seizures related to hypoglycemia should be treated with dextrose (see Table 369-3). Withdrawal from sedative-hypnotic agents such as ethanol or benzodiazepines also cause seizures and is being seen more commonly in adolescents and young adults.

Agitation is a common manifestation of altered mental status and places the patient at risk for injury, hyperthermia, and rhabdomyolysis. Evaluating a highly agitated patient is difficult. Benzodiazepines are the preferred sedative agents, and the dose should be titrated to effect. Extremely agitated patients may require high doses of benzodiazepines to achieve sedation. When multiple doses of the same or different sedative-hypnotic agents are administered over a short period of time, sedation may be associated with respiratory depression and the patient may require endotracheal intubation and ventilatory support.

## Decontamination

Decontamination is considered in 2 large categories: surface decontamination of the skin and eyes and GI decontamination. Because most exposures in children are ingestions, GI decontamination is most commonly considered. In an era when chemical terrorism is a serious concern, however, the issues related to surface decontamination take on added importance.

*Skin exposures* require thorough washing with soap followed by copious rinsing. Eye exposures also require copious irrigation with water or saline. For certain agents such as organophosphate (OP) pesticides or nerve agents, in which significant dermal absorption occurs, decontamination must occur before other interventions, even resuscitation, can proceed. Clothing must be removed and secured. Health care workers involved in the decontamination process must be appropriately protected with gowns and gloves; some exposures require using complete personal protective equipment. If the patient is not appropriately decontaminated, then health care workers are at risk for toxicity from secondary exposure. The prehospital approach to managing chemical incidents includes decontamination at the site of the incident, although decontamination facilities are also found at many health care facilities. Detailed information on decontamination techniques can be found at the Web site of the Centers for Disease Control and Prevention ([http://emergency.cdc.gov/planning/personal\\_cleaningfacts.asp](http://emergency.cdc.gov/planning/personal_cleaningfacts.asp)).

*GI decontamination* refers to any procedure that removes a xenobiotic or reduces absorption from the GI tract and currently includes the use of activated charcoal and whole bowel irrigation (WBI). Syrup of ipecac, gastric lavage, and cathartic agents such as magnesium citrate and sorbitol are *not recommended* as part of the general management of poisoned patients.

Activated charcoal adsorbs most large molecules such as acetaminophen, aspirin, and phenobarbital and can prevent the absorption of these xenobiotics from the GI tract if administered within a short time after ingestion. Activated charcoal does not adsorb small molecules or ions such as lithium or iron. The most common side effects related to activated charcoal administration are vomiting and aspiration. If the patient has a depressed level of consciousness, then the airway must be protected. The use of activated charcoal is contraindicated with GI tract obstruction or perforation. Activated charcoal should not be administered after acid or alkali exposures, especially when endoscopy is planned, because the charcoal will obscure the endoscopist's view of the esophagus and stomach.

The use of activated charcoal may be beneficial in selected cases. The most significant adverse effect of activated charcoal administration is aspiration, and there are some reports of fatal charcoal aspiration. Therefore the risk for activated charcoal aspiration and the discomfort of oral or nasogastric administration may outweigh the benefit in many cases.

WBI involves flushing the entire GI tract with an iso-osmotic electrolyte solution, polyethylene glycol, a procedure frequently used to prepare the bowel for surgery or colonoscopy. In this procedure, large volumes (liters) of polyethylene glycol are infused until

the effluent turns clear, at which point the GI tract is presumed to be empty. WBI is not generally associated with fluid and electrolyte abnormalities, but patients sometimes experience GI discomfort and bloating. WBI may be particularly helpful for agents that cannot be adsorbed to activated charcoal, such as iron or lithium, and for extended-release medications.

## Enhanced Elimination

*Ion trapping*, particularly urinary alkalization, is a method to enhance xenobiotic clearance and is most often used for salicylate poisoning. At physiologic pH levels, salicylate is a weak acid; but in acidosis, salicylate exists mostly in the un-ionized state and can freely traverse cell membranes. When sodium bicarbonate is administered, the bicarbonate ion is excreted in the urine. In alkaline urine, salicylate exists in the ionized state and cannot be reabsorbed across the renal tubule; the salicylate ion has been trapped in the urine. The net effect is to create a concentration gradient that moves salicylate from the CNS into the urine.

Ion trapping may also enhance the elimination of phenobarbital, chlorpropamide, and myoglobin. Theoretically, the elimination of weak bases such as phenylcyclidine and amphetamines should be enhanced in acidic urine. However, urinary acidification has greater risk than benefit and is not used therapeutically.

Hemodialysis provides definitive therapy for a limited number of agents, including ethylene glycol, lithium, methanol, and salicylate. In the past, charcoal hemoperfusion was recommended for theophylline and sometimes for carbamazepine poisonings. However, specialized charcoal cartridges are not generally available, and these poisonings are currently being treated with new high-efficiency, high-flux hemodialysis techniques.

## Supportive Care

Supportive care continues the management outlined in the previous section on Resuscitation, with ongoing attention paid to cardiorespiratory and neurologic status.

Laboratory testing should be directed to the diagnosis of particular xenobiotics or to medical management. A few screening tests are generally appropriate, however, especially for adolescent patients. An electrocardiogram (ECG) can be a useful screening test for agents with characteristic ECG findings such as tricyclic antidepressants or digoxin. Pregnancy testing should be part of the evaluation of adolescent females because suicidal adolescents often have an acute stressor such as pregnancy that precipitates xenobiotic exposure. Because acetaminophen is widely available, because most patients are asymptomatic after acetaminophen ingestion, and because a window exists for antidotal therapy, acetaminophen levels should be assessed after any questionable or suicidal ingestion.

Antidotes are available for many different agents (see Table 369-3). Some of these antidotes are administered empirically during resuscitation or when the history or a toxidrome points strongly to a particular agent. Other antidotes are administered later during the period of supportive care when a specific xenobiotic has been identified.

## SPECIFIC AGENTS

### Analgesics

#### Acetaminophen

Acetaminophen is one of the most commonly used antipyretic and analgesic agents in the United States. It is available in many dosage forms and is formulated in combination with other medications such as opioids, diphenhydramine, dextromethorphan, and pseudoephedrine. Acetaminophen-containing products lead to approximately 7% of all childhood exposures, 4% of all adolescent exposures, and 12% of all childhood and adolescent poisoning fatalities. At therapeutic doses, acetaminophen is remarkably safe. Toxicity occurs after overdose or therapeutic error. Therapeutic dosing errors result from confusion related to the multitude of formulations and strengths and account for many of the childhood fatalities. To reduce the number of medication errors, the FDA currently recommends a single formulation of 160 mg/5 mL (32 mg/mL). Further, the FDA recommends that all dosing for liquid medications be made in milliliters only and that the medication delivery instrument, either syringe or cup, be graduated in milliliters only. In addition, the FDA has recommended that health care professionals discontinue prescribing and dispensing prescription combination products that contain more than 325 milligrams of acetaminophen per tablet, capsule, or other dose unit.

More than 90% of a therapeutic dose of acetaminophen is metabolized by the liver to nontoxic sulfate and glucuronide conjugates. The remainder is metabolized to a toxic intermediate, *N*-acetyl-*p*-benzoquinoneimine (NAPQI), which is conjugated with glutathione to form a nontoxic metabolite. In an overdose, metabolic pathways are saturated, larger quantities of NAPQI are generated, and glutathione stores are depleted. Unconjugated NAPQI causes hepatic necrosis. Young children have relatively larger livers and relatively greater stores of glutathione, which may explain the apparent lower incidence of serious acetaminophen toxicity in children.

After an overdose, patients are usually asymptomatic for the first 24 hours, although they may have some mild GI distress. Clinical hepatitis develops over the next 2 days and may progress to fulminant hepatic failure. Although patients may recover spontaneously, liver transplantation may be necessary in severe cases.

Poison control centers refer patients to the emergency department for evaluation after a single acute ingestion when the ingested dose is unknown; the child is younger than 6 years and the ingested dose is at least 200 mg/kg; or the patient is older than 6 years and the ingested dose is at least 10 g or 200 mg/kg, whichever is lower. GI decontamination with activated charcoal is appropriate. When an otherwise healthy patient takes a single acute overdose of *immediate-release* acetaminophen, the only test necessary is an acetaminophen level performed on samples drawn 4 hours after the exposure. Levels drawn before 4 hours will not reliably predict the need for antidotal therapy. Following a single acute ingestion of an *extended* or *slow-release* preparation, a second level is recommended 4 to 6 hours after the initial 4-hour level (see

below). Additional laboratory testing may be indicated in certain circumstances, such as a case of a mixed overdose, a case of repeat supratherapeutic dosing, when a patient seeks care late, or when an underlying chronic disease is present.

*N*-acetylcysteine (NAC), the specific antidote for acetaminophen overdose, replenishes glutathione (see Table 369-3). The decision to initiate NAC therapy requires using the Rumack-Matthew nomogram (see Figure 369-1). If the level on a sample drawn between 4 and 24 hours after a single acute ingestion is above the *possible toxicity* line (eg, 150 mcg/mL at 4 hours), then the patient should receive NAC. Because the nomogram was developed following single acute ingestions, the applicability of the nomogram to ingestions of extended- or sustained-release formulations or to repeat ingestions of supratherapeutic doses is unclear. In the case of extended-release preparations, if the first or second level (as described previously) is above the treatment line, NAC should be initiated. There is some evidence to suggest that patients whose second level “crossed the line” and had a delayed peak acetaminophen level had massive overdoses or took combination products with agents that can slow GI motility such as diphenhydramine.

Intravenous NAC was approved for use in the United States in 2004 and is the preferred formulation. The incidence of adverse reactions to intravenous NAC administration, primarily anaphylactoid reactions, may be as high as 20%. These side effects are not completely mitigated by lowering the infusion rate, but they are usually amenable to therapy, after

**Figure 369-1** Rumack-Matthew nomogram for deciding whether to use *N*-acetylcysteine (NAC) as an antidote in treating acetaminophen overdose.

which treatment can be restarted. The incidence of these reactions may be increased in patients with lower acetaminophen levels.

Intravenous NAC is reconstituted in 5% dextrose in water and administered according to a complex regimen that delivers a large volume of free water to the patient. As a result, there is a report of a child who developed hyponatremia and seizures while receiving NAC. Intravenous NAC should be administered in consultation with a toxicologist familiar with its use.

The rate of hepatotoxicity is approximately 5% if NAC is administered within 8 to 10 hours of the time of ingestion; after 12 hours, efficacy may be reduced. Therefore, if a patient arrives 4 hours or more after an ingestion and a level will not be available within the 8-hour window, if the patient used an *extended-release* product and a second level is required, or if the patient presents with clinical or laboratory evidence of hepatotoxicity, then NAC should be administered empirically pending the results. Although the efficacy of NAC is reduced after 8 hours, it should still be administered, even to patients who seek care later than 8 hours after the time of ingestion.

Patients in fulminant hepatic failure may require liver transplantation. The King's College Criteria (see Box 369-4) identify patients at increased risk for mortality who should be considered for liver transplantation. Consultation with a transplant team should be initiated early in the course of managing a patient with hepatotoxicity. Spontaneous recovery is not associated with long-term clinical or pathologic sequelae.

If a patient's initial 4-hour acetaminophen level following a single acute overdose of *immediate-release* acetaminophen is below the possible toxicity line of the nomogram, then the patient does not need further medical evaluation. If both a patient's initial 4-hour acetaminophen level and second level drawn 4 to 6 hours later following a single acute overdose of *extended-release* acetaminophen are below the possible toxicity line of the nomogram, then the patient is unlikely to require further medical evaluation. Decisions regarding patients with the ingestion of multiple substances, acetaminophen combination products, *extended-release* products, or repeat supratherapeutic doses should be made with additional consultation of a medical toxicologist.

### Salicylates

Salicylate formulations comprise one of the oldest and most commonly used classes of analgesic and antipyretic medicines and are available in many formulations, including standard, enteric-coated,

extended-release, and chewable tablets. Salicylates are formulated together with opioids and over-the-counter cold remedies, and they can be found in antidiarrheal agents, herbal medications, and analgesic ointments.

Patients ingesting more than 150 mg/kg are at risk for toxicity and generally require direct evaluation. Methyl salicylate is a liquid formulation used as a topical analgesic (oil of wintergreen); a 100% solution contains 1.5 g/mL, and even a single teaspoon of this formulation presents a significant risk for toxicity in a toddler.

Salicylates stimulate the chemoreceptor trigger zone to cause nausea and vomiting and the respiratory center of the medulla to cause hyperpnea and respiratory alkalosis. Salicylates are weak acids that uncouple oxidative phosphorylation and cause a positive anion gap metabolic acidosis. Thus patients may have a respiratory alkalosis, a metabolic acidosis, or a mixed acid-base disturbance. Children usually exhibit acidosis.

Sick patients demonstrate an increased anion gap metabolic acidosis, altered mental status, and hypovolemic shock. Other acute effects include seizures, coma, hyperthermia, hypoglycemia, hypokalemia, and sometimes noncardiogenic pulmonary edema. A laboratory evaluation requires assessment of serum electrolytes, blood gases, and a serum salicylate level. With acute intoxication, mild symptoms are typically seen with salicylate levels as low as 30 mg/dL, although severe toxicity is typically found with levels of 80 to 100 mg/dL. Repeat salicylate levels are indicated for patients with clinical toxicity, with elevated salicylate levels, or in special situations in which the onset of toxicity may be delayed, such as the ingestion of enteric-coated preparations, the possible presence of bezoars, or a history of ingestion of a large dose. Levels should be repeated until there is clear evidence of nonexposure or only low-dose exposure without clinical toxicity or there is a clear trend of decreasing levels associated with clinical improvement. Patients with significant toxicity also need to undergo the repeated measurement of electrolytes and pH.

Ferric chloride can be used as a quick bedside test to confirm exposure to salicylates. Urine that contains salicylate turns purple or brown when 1 or 2 drops of 1% ferric chloride are added to 1 mL of urine. This qualitative test is positive after taking even 1 aspirin tablet; thus proof of salicylism still requires a salicylate level.

The Done nomogram was formerly used to assess the risk for clinical toxicity based on the salicylate level, but its use has fallen out of favor as a clinical tool because it did not predict outcome. Salicylate toxicity is likely with elevated salicylate levels, but toxicity does not specifically correlate with salicylate levels; hence decisions regarding therapy are based on the clinical evidence of toxicity.

Although patients can be quite sick, the need for intubation is unusual, and hypoventilation after intubation may worsen acidosis. Fluid resuscitation is critical, and patients may require treatment for hypoglycemia. Several doses of activated charcoal are useful to prevent the absorption of ingested salicylate and may interrupt salicylate's enterohepatic circulation. Rarely, salicylate tablets form a conglomeration in the

#### BOX 369-4 King's College Criteria

1. Arterial pH <7.3 or lactate >3 mmol/L  
or
2. All of the following
  - a. Creatinine >3.3 mg/dL
  - b. PT >100 sec
  - c. Grade III or IV encephalopathy

stomach that requires surgical removal. In the case of methyl-salicylate, patients may require skin decontamination to prevent ongoing dermal absorption.

The first intervention to enhance salicylate elimination is to alkalinize the urine as described in the previous section on Enhanced Elimination. Optimal elimination occurs when the urine pH is greater than 8. Any patient with clinical evidence of salicylate toxicity is a candidate for alkalization unless administering large volumes of fluid is contraindicated.

Hemodialysis is used to eliminate salicylate and to correct acidosis. Indications for hemodialysis include persistent CNS toxicity; severe, worsening, or intractable acidosis; extremely high salicylate levels (usually >100 mg/dL); or any condition that precludes the administration of a high-volume bicarbonate infusion, such as pulmonary edema, renal insufficiency, or congestive heart failure.

Any patient with evidence of toxicity requires hospital admission for further evaluation and management. If there is no clinical evidence of toxicity after 6 to 8 hours of observation, salicylate levels at that time do not suggest significant exposure, and there is a low risk for delayed absorption as from a bezoar, then the development of subsequent toxicity is unlikely.

## Antidepressants

### Tricyclic Antidepressants

The classic tricyclic antidepressants such as imipramine or amitriptyline have largely been replaced by selective serotonin reuptake inhibitors (SSRIs) as first-line agents in the treatment of depression. Nonetheless, tricyclic antidepressants are still used to augment SSRIs and to treat conditions such as insomnia or neuropathic pain. Tricyclic antidepressant overdose is a leading cause of poisoning morbidity and mortality and ingestion of only 1 or 2 pills may be toxic in a toddler.

Tricyclic antidepressants affect many neurotransmitters and have a myriad of effects. They inhibit norepinephrine and serotonin reuptake from the nerve synapse.  $\alpha_1$ -Adrenergic blockade leads to hypotension. Sodium-channel blockade impairs depolarization throughout the myocardium, leading to prolonged QRS and QT intervals on ECG, right bundle branch block, and wide, complex dysrhythmias.  $\gamma$ -Aminobutyric acid (GABA) receptor inhibition lowers the seizure threshold; brief generalized seizures occur 1 to 2 hours after ingestion. Anticholinergic effects also contribute to delirium, coma, and seizures. The risk for seizures and ventricular dysrhythmias is increased with a QRS duration of more than 100 msec, R-wave amplitude in aVR more than 3 mm, and R/S ratio in aVR more than 0.7.

Because of the high risk for coma, seizures, and dysrhythmias in patients with a tricyclic antidepressant overdose, the benefit of gastric lavage may not outweigh the risk and should only be performed when adequate airway protection is ensured. Reversal agents such as flumazenil and physostigmine are contraindicated in the setting of known or possible tricyclic antidepressant overdose.

The initial management of patients with significant cardiovascular or CNS toxicity follows the principles

outlined in the previous section on Resuscitation. The specific therapy for tricyclic antidepressant-related wide complex ventricular dysrhythmias and hypotension is sodium bicarbonate administration to raise the serum pH to approximately 7.5. A more alkaline pH lowers the concentration of free xenobiotic by stimulating protein binding; the increased serum sodium overcomes the sodium channel blockade. The adverse effects of bicarbonate infusion include volume overload, hyponatremia, and severe metabolic alkalosis.

For refractory hypotension, direct-acting pressors such as norepinephrine are preferred. Extracorporeal cardiovascular support may also be required in appropriate cases.

There are a number of case reports in both adults and children of the successful use of intravenous lipid emulsion therapy to treat cyclic antidepressant toxicity.

Adjunctive therapy for ventricular dysrhythmia includes lidocaine and magnesium. Classes IA, IC, and III antidysrhythmics are likely to exacerbate cyclic antidepressant toxicity.

Benzodiazepines are the preferred treatment for seizures. Barbiturates and propofol may be considered as adjuncts for seizures refractory to benzodiazepines. Phenytoin should not be used because it blocks sodium channels and exacerbates tricyclic antidepressant cardiotoxicity in animal models.

Symptoms of toxicity appear within 6 hours of ingestion. Patients who remain asymptomatic throughout this observation period are unlikely to develop toxicity. Medical admission will be required for patients with signs of cardiovascular or neurologic toxicity.

### Selective Serotonin Reuptake Inhibitors

SSRIs such as fluoxetine, sertraline, and paroxetine are first-line agents for the treatment of depression and anxiety. They increase the synaptic serotonin concentration with little sodium channel, adrenergic, cholinergic, or GABA effect. SSRIs have decreased toxicity in overdose compared with the classic tricyclic antidepressants. The primary adverse effects of SSRIs result from excessive serotonergic stimulation.

*Serotonin syndrome*, a rare but potentially lethal condition, includes altered mental status, agitation, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, and incoordination. If untreated, patients may develop lactic acidosis, rhabdomyolysis with renal failure, hepatic dysfunction, disseminated intravascular coagulation, and acute respiratory distress syndrome. Serotonin syndrome most commonly results from therapy with a combination of serotonergic agents or the combination of an SSRI with a monoamine oxidase inhibitor.

The main focus of therapy of serotonin syndrome is to decrease muscle rigidity and its sequelae, myoglobinuria, and renal failure. Initial therapy for muscle relaxation is with benzodiazepines. Adjunctive therapy may be provided with cyproheptadine, a histamine and serotonin antagonist. Severe hyperthermia should be treated with aggressive cooling. If muscle rigidity is severe and unresponsive to conventional measures, then the patient may require endotracheal intubation with neuromuscular blockade maintained after the patient is intubated.

After acute overdose and following a short period of observation, asymptomatic patients do not require medical admission. Patients with symptoms of serotonin syndrome should be admitted to the hospital for further evaluation and management.

### Antihistamines

Antihistamines are commonly available prescription and over-the-counter allergy medications, antinausea medications, and sleep aids. They are available in both short- and long-acting formulations and are found in combination with other medications such as acetaminophen.

Antihistamines are broadly categorized as  $H_1$ -receptor and  $H_2$ -receptor antagonists. First-generation  $H_1$  antagonists (eg, diphenhydramine) typically cause sedation and CNS depression. Second-generation  $H_1$  antagonists (eg, loratadine) generally have less sedation than the first-generation agents; however, several agents in this class (eg, terfenadine) were withdrawn from the US market because of the high risk for torsades de pointes.  $H_2$ -receptor antagonists such as ranitidine and cimetidine primarily act in the GI tract.

Antihistamine toxicity is marked by either CNS depression with somnolence or coma or by CNS excitation with tremor, hyperactivity, hallucinations, or seizures. Peripherally, antihistamines cause an anticholinergic toxidrome (see Box 369-3). The association of fever and altered mental status may be confused with meningitis or encephalitis.

Most patients with antihistamine toxicity do well with supportive care alone. The administration of activated charcoal is appropriate if it can be administered safely. For large ingestions or for ingestions of sustained-release formulations, WBI may be useful although there are few supportive data. Significant agitation or seizures should be treated with benzodiazepines, as described in the previous section on Resuscitation.

Physostigmine, a carbamate with cholinergic properties, is an antidote for patients with anticholinergic toxicity and is appropriate for use in a pure antihistamine overdose with moderate to severe symptoms (see Table 369-3). The reversal of anticholinergic symptoms after the use of physostigmine is diagnostic, however, because of physostigmine's short half-life, the duration of effect may be shorter than the duration of toxicity. Continued observation after therapy is indicated, and repeat dosing of physostigmine may be necessary.

The adverse effects of physostigmine include seizures, ventricular dysrhythmias, and asystole. Therefore, physostigmine is contraindicated for patients with evidence of cardiotoxicity or for treatment of overdoses of cardiotoxic agents such as tricyclic antidepressants, which may also exhibit anticholinergic effects. Physostigmine therapy should not be administered as nonspecific therapy in patients with coma or agitation of unknown cause.

Patients who remain asymptomatic after 4 to 6 hours of observation generally do not need further medical evaluation. However, symptoms may sometimes be delayed after a large ingestion, and patients may require a longer period of observation.

### Carbon Monoxide

Carbon monoxide (CO), an odorless, colorless, tasteless, and nonirritating gas, is a byproduct of hydrocarbon combustion and is the leading cause of poisoning deaths in the United States. Vehicular exhaust is one of the most common sources of exposure, and children have even been exposed in the back of pickup trucks. House fires are another significant source of unintentional exposure to CO and, in some cases, cyanide. CO exposure also occurs with the use of poorly vented kerosene space heaters, charcoal grills, camping stoves, and gas generators. The paint-stripping agent methylene chloride is converted to CO in vivo and may occasionally cause toxicity. The prevention of CO poisoning involves educating people about the safe use of space heaters and other small CO-generating devices in closed spaces and encouraging the use of CO detectors and smoke detectors in the home and workplace.

The toxic effects of CO poisoning are the result of a variety of mechanisms. CO binds to hemoglobin with a much greater affinity than oxygen and blocks the binding of oxygen. The binding of CO also leads to structural changes in the hemoglobin molecule that decrease the oxygen-carrying capacity and the tissue delivery of oxygen and that shift the hemoglobin-oxygen dissociation curve to the left. CO also binds to myoglobin and impairs oxygen delivery to the heart. The binding of CO to cytochrome oxidase may impair the use of energy that is generated from oxidative phosphorylation. Finally, CO leads to increased nitric oxide production and free radical formation, which causes lipid peroxidation, damage to myelin, and neurotoxicity.

Symptoms of mild CO poisoning can be nonspecific. Headache is the most common symptom. Malaise, nausea, and dizziness may accompany the headache and mimic a nonspecific viral syndrome. Severe disease produces CNS toxicity (altered mental status, seizure, syncope, and coma) and cardiac toxicity (dysrhythmias and myocardial ischemia). Significant toxicity is often associated with metabolic acidosis and increased lactate levels. Cherry-red skin, although frequently mentioned, is rarely seen. Higher carboxyhemoglobin (CO-Hb) levels are associated with more severe disease, but no correlation exists between a particular symptom and a particular level. Children develop symptoms at lower CO-Hb levels than adults.

CO causes lesions in the deep white matter and damage to the thalamus, basal ganglia, hippocampus, and globus pallidus. Neurocognitive deficits, personality changes, focal neurologic symptoms, and movement disorders may be delayed for 2 weeks after exposure. Although children can experience delayed effects, adults have a higher risk, particularly if a loss of consciousness occurs during the early phase of the exposure. Again, these delayed symptoms do not correlate well with the presenting level of CO.

When a pregnant woman is exposed to CO, the fetus is at particular risk. In animal models, peak fetal CO-Hb levels are approximately 10% to 15% higher than and peak later than maternal levels. Brain damage and fetal death have been reported, generally after severe maternal CO exposures.

The best measure of CO exposure is the CO-Hb level. Normal CO-Hb levels are 1% to 2%; smokers may have levels of 5% to 10%. Fetal hemoglobin may be assayed as CO-Hb, and infants may have a CO-Hb of approximately 3%. Standard pulse oximeters cannot differentiate CO-Hb from oxyhemoglobin. Blood gas CO oximetry is necessary to obtain accurate measurements of CO-Hb and methemoglobin. Although levels do not specifically correlate with symptoms, high levels indicate significant exposure. Blood CO-Hb levels fall rapidly after exposure is discontinued, however, postexposure levels may not accurately reflect the maximal exposure in high-demand tissues such as the brain and heart.

Seriously poisoned patients will have impaired CNS and cardiovascular function. Standard PALS and ACLS protocols should be initiated. All exposed patients should initially receive 100% oxygen until an accurate assessment of exposure can be determined or a CO-Hb level can be measured, or both. A pH and blood lactate level should be obtained concurrently because lactate seems to correlate to some extent with the severity of disease and may also suggest exposure to cyanide, which may be produced during a house fire.

The half-life of CO-Hb in a patient breathing room air is 4 to 8 hours but decreases to 1 hour while breathing 100% oxygen and to 15 to 30 minutes when hyperbaric oxygen is administered. Thus, hyperbaric oxygen therapy increases the concentration of dissolved oxygen to displace CO from binding sites on hemoglobin, myoglobin, and cytochrome oxidase; improves the delivery of oxygen to tissues; and reduces lipid peroxidation. Limited data suggest that hyperbaric oxygen therapy reduces the incidence of delayed neurologic and neuropsychiatric effects, particularly if administered within 6 hours, although data are conflicting and specific indications for therapy have not been well defined. Data suggest that hyperbaric therapy is safe for pregnant women and may benefit the fetus. Hyperbaric chambers can be located through the Undersea and Hyperbaric Medicine Web site ([www.uhms.org](http://www.uhms.org)).

Although the use of hyperbaric oxygen for the treatment of severe CO poisoning remains controversial, many experts support its use. Specific indications for hyperbaric therapy have not been clearly defined. Potential candidates include patients with significant CNS, cardiovascular, or neuropsychiatric symptoms; persistent metabolic acidosis; ECG changes or clinical symptoms that do not respond to standard 100% oxygen therapy; CO-Hb level exceeding 25%; or, in pregnant women or children, a CO-Hb level exceeding 20%. Decisions regarding the potential utility for any particular patient should be made in consultation with a medical toxicologist or a hyperbaric specialist.

In general, symptomatic patients require hospitalization for further evaluation and management. Patients with relatively low CO-Hb levels and mild symptoms, especially when symptoms resolve after a short course of oxygen therapy, do not require hospitalization. Identifying and ameliorating the source of CO is imperative; identifying other potentially exposed persons who may require evaluation is also important.

## Cardiovascular Medications

Although childhood poisoning with cardiovascular agents is unusual, even small doses may cause serious toxicity. Four classes of cardiovascular agents are reviewed here: cardiac glycosides, calcium channel antagonists (CCBs),  $\beta$ -adrenergic antagonists (BBs), and  $\alpha_2$ -adrenergic agonists.

### Cardiac Glycosides

Cardiac glycosides include digoxin, digitalis, and related compounds found in plants such as oleander and foxglove and in some toad venoms (bufotoxin). Bufotoxins have become popular as hallucinogens and aphrodisiacs, and their use has resulted in death.

The cardiac glycosides inhibit myocyte sodium-potassium adenosine triphosphatase pumps and increase the concentration of intracellular sodium and calcium during systole. Cardiac glycosides increase inotropy and automaticity, shorten repolarization intervals, and decrease conduction through the sinoatrial and atrioventricular (AV) nodes. The result is to increase the force and velocity of myocardial contractions.

Symptoms associated with acute overdose are typically nausea, vomiting, headache, weakness, confusion, changes in vision, palpitations, and dizziness. A severe acute overdose leads to hyperkalemia, bradycardia, hypotension, and dysrhythmia. Hypercalcemia, hypokalemia, hyperkalemia, or hypomagnesemia can exacerbate cardiac toxicity. A chronic overdose is often characterized by nausea and vomiting, psychiatric disturbances, drowsiness, headache, and hallucinations.

A serum digoxin level drawn 4 to 6 hours after ingestion assists in management. Levels above the therapeutic range may be associated with toxicity; higher levels are generally associated with a higher risk for and more serious toxicity. Children may tolerate high digoxin levels with less clinical toxicity. The laboratory assays used to measure digoxin cross-react incompletely with plant- and toad-derived digoxin-like substances; thus an increased digoxin level may at least indicate exposure to one of these substances. Specific digitoxin levels are sometimes available.

Activated charcoal and steroid-binding resins such as cholestyramine adsorb cardiac glycosides in the GI tract and may interrupt their enterohepatic circulation. Hyperkalemia should be aggressively treated with bicarbonate, insulin, and glucose. Calcium administration is contraindicated for the treatment of hyperkalemia in this setting because it can exacerbate glycoside toxicity, but magnesium sulfate should be used in patients with hypomagnesemia. Kayexalate can also be administered.

Significant toxicity is treated with digoxin-specific antibody antigen-binding fragments (Fab) (see Table 369-3). In the acute setting, Fab therapy is used to treat significant dysrhythmia, serum digoxin levels of more than 15 ng/mL at any time or more than 10 ng/mL 6 hours after ingestion, a serum potassium level of more than 5 mEq/L, hypotension, second- or third-degree heart block, or a digoxin dose of more than 10 mg in a teenager or adult or more than 4 mg in a child. The administration of Fab causes a marked increase in the measured serum digoxin

level; therefore, post-treatment levels do not reliably indicate a response to therapy.

Adjunctive therapy includes atropine for bradycardia and phenytoin and lidocaine for ventricular dysrhythmias. Cardioversion should be avoided because the ensuing sympathetic discharge can be fatal. Classes Ia, Ic, II, and IV antidysrhythmics are contraindicated because they decrease AV conduction and worsen bradycardia and other dysrhythmias.

### **$\beta$ 1-Adrenergic Antagonists and Calcium Channel Antagonists**

$\beta$ -Adrenergic antagonist medications (BBs) such as propranolol, atenolol, and metoprolol are commonly prescribed for the treatment of hypertension, angina, dysrhythmias, and headache.  $\beta_1$ -Receptor blockade results in decreased myocardial contractility and conduction;  $\beta_2$ -receptor blockade increases smooth muscle tone (bronchospasm) and peripheral vascular tone (hypertension).

After an oral overdose of BBs, symptoms begin within 2 hours; sustained-release formulations may result in delayed onset. Cardiovascular manifestations include hypotension, bradycardia, wide QRS and PR intervals on ECG, bundle branch block, and ventricular dysrhythmias such as ventricular tachycardia and torsades de pointes. CNS depression ranging from drowsiness to coma and seizures can also occur. Bronchospasm may occur in patients with a history of asthma. Metabolic effects include hyperkalemia and hypoglycemia.

Calcium channel antagonists (CCBs) such as verapamil, diltiazem, and nifedipine are used to treat hypertension, angina, and cardiac arrhythmias and are available in both immediate-release and long-acting formulations.

Calcium channels are found in the sinoatrial and AV nodes, the myocardium, and vascular smooth muscle. CCBs block the influx of calcium into myocytes and reduce contractility and conduction; smooth muscle relaxation also occurs. CCBs cause sinus bradycardia, hypotension, AV block, CNS depression, hyperglycemia, and lactic acidosis.

CCB and BB overdoses are clinically similar. For both BB and CCB ingestions, activated charcoal can be administered. WBI should be considered for ingestions of sustained-release preparations. Glucagon is considered a specific antidote for significant hypotension and bradycardia associated with BB overdose, but it may also be useful for CCB ingestions. Glucagon increases cyclic adenosine monophosphate (cAMP) activity, leading to positive inotropy. High-dose insulin and glucose are another therapeutic option; insulin may increase myocardial glucose use or alter myocardial calcium handling. There are case reports of the successful use of intravenous lipid emulsion for both BB and CCB poisoning. Calcium chloride may be useful after CCB or BB overdose. There may be a role for phosphodiesterase inhibitors such as milrinone, which also inhibit the breakdown of cAMP, in select cases.

Table 369-3 provides additional information on glucagon, insulin, intralipid emulsion therapy, and calcium.

In both CCB and BB overdose, adjunctive therapy for severe refractory bradycardia includes atropine,

epinephrine, isoproterenol, and cardiac pacing. Patients may require therapy for hyperglycemia, hyperkalemia, or seizures.

All symptomatic patients with a history of a BB or CCB overdose should be admitted to an intensive care unit. Patients with exposure to a sustained-release preparation should be admitted for observation. Patients who remain asymptomatic for at least 6 hours after exposure to an immediate-release product may be discharged.

### **$\alpha_2$ -Adrenergic Agonists (Clonidine)**

Clonidine is used to treat hypertension and other disorders such as attention deficit/hyperactivity disorder and nicotine withdrawal. Oral and patch formulations are both available. Even 1 or 2 clonidine pills may cause toxicity in a toddler. The patches contain high doses of clonidine to ensure transdermal delivery, and they are a particular problem when ingested by children.

Clonidine stimulates central  $\alpha_2$ -adrenergic receptors and can modulate opiate receptors. At therapeutic doses, clonidine primarily affects  $\alpha_2$  receptors, but at high doses, both  $\alpha_1$  and  $\alpha_2$  receptors can be stimulated.

Toxic symptoms begin within 1 hour of ingestion and can last up to 24 hours. Clonidine toxicity mimics opioid toxicity, with altered mental status, coma, respiratory depression, and miosis. Hypotension and bradycardia may develop, and dysrhythmias such as first- and second-degree AV block may also occur.

Naloxone should be administered in cases of respiratory depression; high doses may be required (see Table 369-3). Naloxone may also be useful in cases of CNS depression or hypotension. When naloxone is effective but clonidine toxicity outlasts naloxone's effect, a continuous infusion of naloxone is indicated. Decontamination with activated charcoal is appropriate, and WBI may be indicated for children who have ingested clonidine patches. Atropine may have modest effects on bradycardia, and fluids and pressors are indicated for hypotension.

Patients may be discharged if they are asymptomatic 4 hours after ingestion. All symptomatic patients should be admitted to the hospital.

### **Caustic Ingestions**

Caustic agents are broadly categorized as *acids* and *alkalis*. Common sources of acid in the home include toilet bowl cleaners, rust removal products, and automotive battery liquids. Common alkaline-containing products include drain cleaners, bleaches, ammonia-containing cleaners, oven cleaners, dishwasher detergents, and hair relaxers. Serious caustic exposures are unusual in childhood, but these agents have the potential to cause significant injury with even small exposures.

Acids injure tissue by coagulation necrosis. Even though the resulting eschar might theoretically limit the initial depth of injury, esophageal, gastric, or intestinal injuries frequently occur. Significant exposures may cause metabolic acidosis or acute renal failure.

Alkali ingestions injure tissue rapidly by liquefaction necrosis. Within minutes, tissue edema develops in the oropharynx and esophagus, potentially leading to airway obstruction. Over several weeks, scar tissue

from full-thickness burns in the esophagus may progress to form strictures.

Caustic ingestions produce dysphagia, odynophagia, drooling, stridor, hoarseness, abdominal pain, nausea, and vomiting. GI hemorrhage and perforation may occur. A tissue eschar may sometimes mask findings despite a significant acid ingestion.

A gastric lavage is generally contraindicated after caustic ingestions because of the risk for esophageal or gastric perforation. In the case of large-volume acid ingestions, nasogastric suction performed within 30 minutes of exposure may prevent the passage of acid into the small intestine. Activated charcoal adsorbs caustic chemicals poorly and may interfere with endoscopy and is therefore not recommended. Plain-film radiographs of the chest and abdomen are helpful to assess pneumomediastinum, pneumoperitoneum, and aspiration pneumonitis. Esophagoscopy defines the extent of injury and should be performed in symptomatic patients.

Almost all significant caustic exposures require admission for endoscopy. If any suspicion of perforation exists, then a surgical consultation should be obtained and broad-spectrum antibiotics should be administered. The neutralization of acids and bases should be avoided because of the excessive heat this generates and the risk for emesis. A repeat esophagram will be required 3 to 4 weeks after caustic ingestion to check for strictures.

### Hydrocarbons

Hydrocarbons are organic compounds that have significant toxicity. They are broadly categorized into 3 classes: aliphatics (kerosene, gasoline, mineral seal oil, solvent, paint thinners), aromatics (industrial solvents such as benzene and toluene), and terpenes (turpentine and pine oils). Hydrocarbon aspiration after unintentional exposure to such household products is a leading cause of poison-related death in young children.

Pulmonary toxicity results from chemical pneumonitis after aspiration. Local or diffuse infiltrates, pleural effusions, and pneumatoceles may develop. Lipoid pneumonitis may result from aspirating hydrocarbons with high viscosity, such as petroleum jelly.

Most patients will experience some coughing after hydrocarbon exposure, but cough does not by itself indicate pulmonary toxicity. Significant exposures cause gasping, choking, gagging, and vomiting that begins within 30 minutes, and patients may develop cough, tachypnea, rales, rhonchi, wheeze, and diminished breath sounds. In the most severe cases, acute lung injury, hemorrhagic pulmonary edema, and respiratory failure may occur with long-term respiratory dysfunction. Respiratory effects may progress over the first 24 hours and resolve over the ensuing 2 to 5 days. Associated acute symptoms may include CNS depression and fever.

Contaminated clothing should be disposed of properly, and the skin should be washed with soap and water to limit continuing exposure to hydrocarbon vapors. GI decontamination plays only a limited role; toxicity is related more to pulmonary exposure than to GI absorption. Most patients experience nausea and

vomiting after hydrocarbon exposure and do not require further gastric emptying. Gastric emptying is contraindicated after most hydrocarbon ingestions because the risk for aspiration increases with any gastric-emptying procedure.

Symptomatic patients have radiographic evidence of aspiration as early as 30 minutes after exposure. Asymptomatic patients occasionally develop radiographic changes, but the importance of these changes is unclear.

The management of pulmonary toxicity includes supplemental oxygen, humidified air, and intravenous fluids. Nebulized  $\beta_2$ -receptor agonists may be useful. Severely ill patients may require continuous positive airway pressure, mechanical ventilation with positive end-expiratory pressure, or extracorporeal membrane oxygenation. Corticosteroids are not beneficial in hydrocarbon ingestions. Leukocytosis and fever are associated with hydrocarbon aspiration and, at least early in the course, do not signify infection.

Patients with persistent respiratory symptoms should be hospitalized. Patients who are asymptomatic or whose initial symptoms have resolved and whose radiographic findings are normal should be observed for 6 hours. If a patient remains asymptomatic after 4 to 6 hours of observation, then the patient generally does not need further medical evaluation.

### Iron

Despite consumer product safety improvements, iron poisoning remains a problem for toddlers. Prenatal vitamins typically contain 62 mg of elemental iron per tablet and can resemble candies such as M&Ms or Good & Plenty, making them appealing to children. Most significant toxicity is related to ingestion of adult iron tablets, not children's liquid or chewable vitamin preparations.

Iron is a GI irritant that causes abdominal pain, nausea, vomiting, and diarrhea. Severe poisoning causes mucosal ulceration and hemorrhagic necrosis, leading to hematemesis, melena, or hematochezia. GI fluid losses lead to hypovolemic shock and contribute to positive anion gap metabolic acidosis. Absorbed iron leads to the production of free radicals, with adverse effects on cellular metabolism, which exacerbate the acidosis. The combination of the shock state and iron's direct toxic effects contributes to progressive myocardial dysfunction and acute hepatic injury. As hepatocellular damage progresses, coagulation is disrupted, further exacerbating the GI hemorrhage. In rare cases, corrosive injury to the GI tract leads to gastric outlet obstruction weeks after the ingestion.

In general, the higher the dose of iron ingested, the greater the likelihood of toxicity (see Table 369-4). Poison control centers typically refer patients for evaluation if the ingested dose of elemental iron is more than 20 mg/kg. Similarly, the higher the serum iron level, the greater the likelihood of resultant toxicity (see Table 369-4). A peak serum iron level is best measured 4 to 6 hours after ingestion.

GI symptoms alone do not necessarily predict severe toxicity but do confirm exposure. Because GI distress is a marker of exposure, asymptomatic patients do not require gastric emptying. Patients experiencing toxicity

**Table 369-4**  
**Iron Toxicity Based on Dose and Serum Iron Level**

INGESTED DOSE <sup>a</sup>	EXPECTED TOXICITY
<20	None or minor
20–40	Mild to moderate
40–60	Moderate to severe
>60	Severe
Serum iron level (mg/dL)	Expected toxicity
<300	None or minor
300–500	Mild to moderate
>500	Severe

<sup>a</sup>Ingested dose of elemental iron (mg/kg).

vomit spontaneously, and in these cases, no additional benefit exists to gastric emptying.

Nonetheless, a limited role for gastric decontamination exists after a significant ingestion or when a large number of pills are radiologically evident in the stomach or GI tract. WBI may be effective in removing these pills. In rare cases, surgery may be necessary to remove the iron pills.

Radiographs detect residual iron pills in less than 3% of all ingestions. However, the absence of pills on radiographs does not exclude a toxic overdose. In particular, chewable and liquid iron formulations do not appear on abdominal radiographs, but they do not account for most toxic exposures.

Although significant iron poisoning is associated with both an increased serum glucose and an increased white blood cell count, normal values do not rule out significant exposure. A total iron-binding capacity greater than the serum iron level was once thought to be protective in poisoning; however, the total iron-binding capacity is factitiously increased in the setting of iron poisoning. Deferoxamine also interferes with the accurate measurement of total iron-binding capacity.

In addition to the initial GI symptoms, patients with significant poisoning are in shock with a positive anion gap metabolic acidosis. These patients are very ill and need immediate and vigorous resuscitation. Although a serum iron level might be useful because the optimal time to draw the level would be 4 to 6 hours after exposure and because results may be delayed, decisions regarding treatment will usually have to be made on clinical grounds alone.

Chelation therapy with deferoxamine should be considered for any symptomatic child who is in shock, has an altered mental status, or is experiencing protracted vomiting or GI bleeding (see Table 369-3). Serum iron levels exceeding 500 mcg/dL or abdominal radiographs suggesting a serious ingestion may also be an indication for chelation. Desferrioxamine, the deferoxamine-iron chelate, is excreted in the urine and imparts a dark brown or *vin rose* color to the urine. This color change is only a qualitative measure of desferrioxamine and is an unreliable marker of iron elimination. Chelation therapy

should continue until the child is clinically improved and the metabolic acidosis is resolved, but a duration of therapy greater than 24 hours may present an increased risk for toxicity.

Patients who remain asymptomatic without treatment for 6 hours after ingestion generally do not need further medical evaluation.

### Isoniazid

Isoniazid (isonicotinyl hydrazine [INH]) is a medication primarily used for the prophylaxis and treatment of tuberculosis. It can cause hepatic toxicity, peripheral neuropathy, and optic neuritis even at therapeutic doses. INH doses of more than 30 mg/kg are likely to cause acute toxicity. Effects occur within 2 hours of ingestion. Patients initially experience nausea, vomiting, slurred speech, dizziness, tachycardia, urinary retention, and hyper-reflexia or hyporeflexia. Significant toxicity causes an anion gap metabolic acidosis, coma, and refractory seizures. INH inhibits the effects of vitamin B<sub>6</sub> (pyridoxine), an essential cofactor for the synthesis of GABA, an inhibitory neurotransmitter. Seizures occur as a result of decreased GABA activity.

If an asymptomatic patient seeks care soon after a significant exposure, then activated charcoal may be provided. To prevent seizures, prophylactic pyridoxine should be administered to patients who seek care within 2 hours of ingestion.

Seizure therapy can begin with benzodiazepines; phenytoin is not useful in treating INH-related seizures. Definitive seizure therapy requires administration of pyridoxine, the specific antidote for INH toxicity (see Table 369-3). If intravenous pyridoxine is unavailable, then crushed tablets can be given by nasogastric tube. Hemodialysis may be considered for patients with massive toxic ingestions.

Patients who remain asymptomatic for 6 hours generally do not need further medical evaluation.

### Lead Poisoning

Public health efforts during the past 2 decades have dramatically reduced environmental lead exposure by limiting its concentration in automotive gasoline and paints. Nonetheless, lead poisoning remains a significant public health concern. In 2012 the Centers for Disease Control and Prevention (CDC) recommended a new reference blood lead level (BLL) of 5 mcg/dL based on the 97.5th percentile of the BLL distribution among children 1 to 5 years old in the United States. The CDC estimates that approximately 450,000 children in the United States have BLLs higher than this reference value.

In this regard the prevention of any lead exposure, even before conception, is the primary goal as opposed to screening for and treatment of elevated blood levels.

The principal childhood source of lead is from deteriorating paint in houses built and painted before 1978. Although pica may result in oral lead exposure, more children are exposed to aerosolized lead paint flakes or contaminated dust inside the home or in the soil. Other sources of lead include lead-based plumbing, ceramics, or imported goods in lead-soldered

cans. Folk remedies for colic advocated by some Chinese, South Asian, and Hispanic cultures may also result in lead exposure. Prenatal exposure to lead is another source for concern.

Gastrointestinal absorption of ingested lead is facilitated by deficiencies in essential trace elements such as iron, calcium, and zinc, which compete for the same absorption sites. Absorbed lead is bound to erythrocytes and distributed into relatively labile soft tissue storage sites such as the liver and brain and into more stable reservoirs such as bone. Although the inhalation of lead fumes occurs in occupational exposures among adults, in children, aerosolized lead particles are inhaled, coughed up, and swallowed.

Lead inhibits heme biosynthetic enzymes, producing a hypochromic, microcytic anemia. Lead also interferes with vitamin D biosynthesis, impairing calcium metabolism. Chronic lead poisoning can produce a reversible but progressive lead nephropathy with a Fanconi-like syndrome of glycosuria, aminoaciduria, and phosphaturia. As lead accumulates in the CNS, it compromises the capillary endothelium, causing cerebral edema and increased intracranial pressure. Irreversible neuronal damage and alterations in neurotransmitter function can also cause more subtle neurocognitive disabilities.

The initial clinical manifestations of chronic lead poisoning are subtle; most children with a history of lead exposure and absorption are asymptomatic. Pallor, hearing impairment, constipation, and behavioral disturbances may be the first signs of chronic lead poisoning, but a loss of developmental milestones and declines in school performance are sometimes seen. A threshold no-effect level for lead has not been defined, and decreased IQ has been observed in children with whole blood lead (BPb) levels less than 10 mcg/dL.

Encephalopathy is one of the more dramatic clinical manifestations of lead toxicity. Children with BPb levels that exceed 70 mcg/dL may experience coma, intractable seizures, or even death. Patients with BPb less than 70 mcg/dL may exhibit ataxia, incoordination, lethargy, or irritability. Subacute encephalopathy may cause anorexia, intermittent abdominal pain, nausea, vomiting, or constipation. Peripheral neuropathy is uncommon in children, but wrist and foot drops may occasionally occur with sickle cell disease.

In all cases of suspected lead poisoning, any sources of lead exposure should be identified and abated, and parents should be counseled regarding optimal nutrition. Most children with lead exposure are asymptomatic, but many are hospitalized to remove them from further exposure. Symptomatic children are also hospitalized to remove them from the source of lead and to administer chelation therapy. If abdominal radiography finds radiopaque material, then WBI with polyethylene glycol should be initiated.

Chelation therapy is reserved for symptomatic children or those with modest to severe lead burdens (BLL >45 mcg/dL); blood lead levels less than 45 mcg/dL represent excessive exposure to lead but do not require chelation therapy. Three lead chelating agents are available in the United States: dimercaprol (also known as British anti-lewisite [BAL]), CaNa<sub>2</sub>EDTA,

and succimer (dimercaptosuccinic acid [DMSA]) (see Table 369-3). A fourth agent, D-penicillamine, is not approved by the FDA, but its use may be necessary in the unusual event of adverse reactions to both DMSA and CaNa<sub>2</sub>EDTA. CaNa<sub>2</sub>EDTA (*calcium* disodium EDTA) used for lead chelation must not be confused with Na<sub>2</sub>EDTA (disodium EDTA), which can cause severe hypocalcemia.

Asymptomatic children with BPb between 45 and 70 mcg/dL are chelated with oral succimer; intravenous CaNa<sub>2</sub>EDTA is also an option. Children with BPb more than 70 mcg/dL are chelated in the hospital with intramuscular BAL and intravenous CaNa<sub>2</sub>EDTA. Encephalopathy is treated with the same 2-medication regimen but for a longer course. After initial chelation therapy, the decision to repeat treatment depends on symptoms and subsequent BPb levels.

### Organophosphates Pesticides

Organophosphate (OP) agents such as parathion or malathion are highly toxic compounds that are found in a variety of pesticides. Ingestion of the agent directly or of contaminated fruit is the most common route of exposure in children, although these agents are highly lipophilic and are well absorbed through the skin, eyes, and lungs. Assistance in identifying individual agents can be obtained from the US National Pesticide Telecommunications Network at 800-858-7378 or npic.orst.edu.

OPs bind to and inactivate acetylcholinesterase; acetylcholine accumulates in nerve terminals of the autonomic nervous system and CNS and at the neuromuscular junction. This bond, which is initially reversible, becomes permanent after a 24- to 48-hour period. After inactivation is permanent, new acetylcholinesterase must be synthesized.

Acute OP poisoning causes cholinergic symptoms (see Box 369-3). CNS symptoms are often the presenting symptoms in younger children. The diagnosis of OP poisoning is made when a patient has a confirmed exposure or a history of a suspected exposure and consistent physical findings. The hydrocarbon carrier may produce an odor of garlic. Symptoms occur within several hours but may be delayed for several days with the more fat-soluble compounds.

The poisoned patient has pinpoint pupils, vomiting, changes in mental status, and copious secretions. Untreated, the combination of bronchial hypersecretion, bronchial constriction, and the failure of respiratory musculature leads to respiratory failure, which may be complicated by coma and convulsions. Atypical presentations can occur in children. For example, a child might have only mydriasis and tachycardia. Other clinical sequelae that have been reported in children include hyperglycemia, metabolic acidosis, and prolongation of the QT interval with subsequent torsades de pointes.

The *intermediate syndrome*, uncommon in children, describes delayed toxicity that occurs after the resolution of initial cholinergic symptoms. Symptoms include proximal muscle weakness, cranial nerve deficits, and hyporeflexia. These symptoms are present 1 to 3 days after the cholinergic crisis, are not

responsive to atropine, and require supportive care for several weeks. An increased risk for the intermediate syndrome seems to exist with the more lipophilic agents, which may not have been accessible to antidote and which are released from fat-storage sites into the circulation. Delayed polyneuropathy, ataxia, neuropsychiatric symptoms, peripheral neuropathy, and spasticity have also been reported up to 3 weeks after exposure. Most of these cases improve with time and do not cause permanent disability.

Although serum levels of both butyrylcholinesterase (pseudocholinesterase) and red blood cell cholinesterase (true cholinesterase) can be measured, red blood cell cholinesterase is a more sensitive measure of OP toxicity. However, red blood cell cholinesterase testing is not available in most hospital laboratories. Treating a patient for a suspected OP poisoning should not wait for laboratory confirmation.

When a patient seeks care for a suspected or confirmed OP exposure, decontamination should follow the principles outlined earlier in this chapter. Rescuers and health care workers are at risk for exposure if a patient has not been appropriately decontaminated. Contaminated clothing must be safely discarded. For ocular exposures, the eyes should be copiously irrigated. After ingestions, activated charcoal can be administered.

The immediate life-threatening problem is bronchorrhea (copious airway secretions). A patient in severe respiratory distress should be intubated, and atropine should be administered (see Table 369-3). Succinylcholine should not be used for rapid-sequence intubation because it requires the inactivated cholinesterase for its metabolism. The goal of therapy is to dry the airway secretions with atropine. High-dose, continuous infusions of atropine may be required. Tachycardia, which may be related to atropine administration but which may also be related to hypoxia, is not a contraindication to the use of higher doses of atropine.

The OP-acetylcholinesterase enzyme complex ages over time, leading to irreversible inactivation of the enzyme. 2-Pralidoxime, also known as 2-PAM, can hydrolyze the bond and reactivate the cholinesterase when administered before complete aging. Because this agent does not cross the blood-brain barrier, the reversal of neurologic symptoms requires atropine. Pralidoxime's efficacy varies with the different OP compounds, but it should be administered in all cases of severe toxicity.

All patients with OP toxicity require admission. The time to full recovery depends on the agent and can range from a few hours to several weeks.

### Nerve Agents

Organophosphate compounds that were too toxic to be used as pesticides were developed as nerve agents in the 1940s. Sarin, soma, tabun, and VX are all agents with very rapid rates of permanent cholinesterase inactivation, leading to the rapid onset of severe cholinergic symptoms. These agents can be dispersed through a blast or can be aerosolized. Sarin, soma, and tabun are volatile liquids with easily inhaled fumes. VX is less volatile than the others and is more

likely to be absorbed through the skin. The volatile fumes of sarin, soma, and tabun are quickly dispersed in the air and degrade within several hours. Patients exposed to these agents are not at further risk after they are removed from the site of exposure. VX is more persistent in the environment and may present a risk for ongoing exposure. Overall, these agents are more dense than air and are concentrated near the ground; thus children may have an increased exposure risk. More information on OPs and nerve agents with potential for use as chemical weapons can be found at [www.bt.cdc.gov/agent/nerve](http://www.bt.cdc.gov/agent/nerve).

The treatment for these agents is the same as that outlined for OP insecticides previously. In June 2003, the FDA approved an atropine autoinjector for children that is available for prehospital use.

### Plants

Plant exposures are common in children because plants are easy to reach in the home and environment. More than 750 toxins have been identified in more than 100 plant species. Plants do not require labeling for potential toxins as is done for pharmaceuticals and household products, and no federal regulations exist on sales of plants or herbs.

Exposure to plants occurs by contact with the skin or eyes or by ingestion. Although plant exposures are common, only a very few patients seek medical attention, and even fewer require intervention. For example, common plants such as the dandelion pose little hazard. The most common plants that result in clinical sequelae are peace lily, holly, philodendron, poinsettia, pokeweed, poison ivy, rubber tree, and nightshade (see Table 369-5).

Prevention of plant exposures occurs through education. Parents must learn the names of the plants they purchase, be familiar with plants that are toxic, and keep them safely away from children.

### Substance Abuse

The high prevalence of ethanol and substance use among adolescents despite educational efforts makes it an important issue for parents and health care providers alike. Ethanol and marijuana are the substances most commonly used by adolescents in the United States followed by prescription drug abuse (see Table 369-6). Use of most other substances have shown some decline over recent years. The recognition of substance use is a challenging but necessary skill of any pediatrician. The primary outpatient management of substance use and abuse is beyond the scope of this chapter.

### Marijuana

Marijuana is made from the dried leaves of the plant *Cannabis sativa*. Extracts of the *Cannabis* plant are available as hashish (dried resin) and hash oil (liquid extract). These various forms can be smoked or eaten. Medical marijuana is available in pill form (Dronabinol).

The active component in marijuana is tetrahydrocannabinol (THC), a lipophilic and psychoactive compound that easily crosses the blood-brain barrier. When inhaled, the onset of action is 10 to 30 seconds, and the effects last from 1 to 4 hours. Ingestion results

**Table 369-5**      **Toxic Plants**

PLANT	TOXIN OR TOXIC PART	TOXICITY AND TREATMENT
<b>HOUSEPLANTS AND CULTIVATED FLOWERS</b>		
Aloe	Latex contains anthraquinones	Oral irritation, nausea, vomiting, diarrhea
Anemone	Protoanemonin aglycone	Irritation of mucous membranes and GI
Autumn crocus, glory lily	Colchicine	GI, respiratory, renal, CNS toxicity
Christmas pepper	Capsicum	Strong irritant, stinging or burning of mucous membranes
Chrysanthemum	Sesquiterpene, lactones, pyrethrins	Skin reactions
Iris	Resin-like podophyllotoxin	Gastroenteritis
Jerusalem cherry	Solanine alkaloids	GI, CNS depression
Lily of the valley, foxglove, oleander	Cardiac glycosides	Irritation of mucous membranes, CV toxicity
Monkshood, larkspur	Alkaloid aconitine	Restlessness, salivation, irregular heartbeat Rx: gastric decontamination
Narcissus, amaryllis, daffodil	Alkaloid lycorine	Vomiting and diarrhea
Philodendron, caladium, dumb cane, elephant ear, peace lily, pothos	Oxalates	Irritation of buccal mucosa, edema, gastroenteritis, hypocalcemia Rx: rinse mouth with milk; administer calcium
Snow on the mountain	Unknown acrid principle in milky sap	Irritation of mucous membranes and GI
<b>WILDFLOWERS AND WEEDS</b>		
Buttercup, morning glory	Protoanemonin; seeds contain lysergic acid monoethylamide	GI irritation, CNS stimulation, hallucinations
Deadly or black or climbing nightshade, jimson weed, henbane	Atropine, solanine, and related glycoalkaloids	Anticholinergic Rx: physostigmine
Death camas	Veratrum alkaloids	Nausea, vomiting, hypotension, bradycardia, syncope, paresthesia, weakness Rx: atropine
Green or false hellebore	Veratrum alkaloids	GI irritation, respiratory, CV depression Rx: atropine
Horse nettle	Solanine alkaloid	GI, CNS depression
Jack-in-the-pulpit, wild calla, skunk cabbage	Calcium oxalate crystals	Irritation and burning of mouth Rx: rinse with milk and magnesium hydroxide
May apple	Podophylloresin	May produce peripheral neuropathy, vomiting, colic, diarrhea, drowsiness, impaired vision
Poison hemlock	Alkaloid coniine	Salivation, nausea, vomiting, diarrhea, sensory disturbances, seizure, coma; death from respiratory paralysis
Poison ivy, oak, sumac, wood	Urushiol	Rhus dermatitis—red, itchy, and clear blisters that exude serum; if ingested, causes severe mucosal irritation Rx: topical or oral corticosteroids
Pokeweed	Podophyllotoxins	Vomiting, sweating, colic, diarrhea, CNS depression
Rosary pea	Abrin	Burning sensation of mouth and throat, delayed GI, depression of vasomotor center, CV collapse
Spurges	Unknown acid principle	Severe mucosal irritation
Water hemlock	Cicutoxin	Generalized seizures Rx: symptomatic to prevent or control seizures
White snakeroot	Tremetol, may be in milk of poisoned cow	Weakness, vomiting, tremor, and death
<b>CULTIVATED FLOWERS AND CROPS</b>		
Castor bean	Ricin, must be chewed to release	Burning sensation of mouth and throat, delayed GI, depression of vasomotor center, hepatic, hemolysis, convulsions, and death

Continued

**Table 369-5** Toxic Plants—cont'd

PLANT	TOXIN OR TOXIC PART	TOXICITY AND TREATMENT
Potato, tomato	Foliage and sprouts contain solanine alkaloids	GI irritation, headache, CNS depression, dermatitis
Rhubarb	Leaves contain oxalate crystals and soluble oxalates	Irritation of mucosa, hypocalcemia with seizures Rx: rinse mouth with milk, replace calcium
Tobacco	Nicotine	Salivation, gastroenteritis, seizures
<b>TREES AND WOODY SHRUBS</b>		
Black locust	Toxalbumin	Anorexia, weakness, GI, dilated pupils, irregular and weak pulse
Cherry, apple, peach, apricot, choke cherry	Leaves, pits, or seeds contain glycosides hydrolyzed to hydrocyanic acid on chewing	Dyspnea, paralysis, convulsions, coma, and death Rx: cyanide antidote kit
Daphne	Glycoside in which the aglycone is dihydroxycoumarin	Burning and irritation to the skin and GI tract, bloody diarrhea, stupor, weakness, and convulsions
English holly	Ilexanthin and ilex acid	Vomiting and diarrhea
Mistletoe	Berries contain lectins, phoratoxin, viscotoxin, polysaccharides	Gastroenteritis and CV collapse
Mountain laurel, rhododendrons	Grayanotoxin	Local and GI irritation, respiratory and CV depression Rx: atropine
Yew	Alkaloid taxine	Vomiting, colic, hypotension, respiratory depression

CNS, Central nervous system; CV, cardiovascular; GI, gastrointestinal; Rx, treatment.

Been offered, gave, or sold illicit substance at school	22		

<sup>a</sup>Current and first use reported only for ethanol and marijuana. Data from Centers for Disease Control and Prevention (CDC): Youth risk behavior surveillance—United States, 2013. *MMWR Morb Mortal Wkly Rep Surveill Summ*. 2014;63:1–172.

in slower onset of action (30 to 60 minutes) and more prolonged effects. THC stimulates cannabinoid receptors, activates the mesolimbic dopaminergic pathway (the reward pathway), and increases turnover in the GABA pathway. THC metabolites accumulate in adipose tissue and can be detected by urine toxicologic screens up to 1 month after use.

The clinical effects of marijuana include euphoria, impaired motor coordination and speech, impaired short-term memory, paranoia, and agitation. In rare circumstances, patients may experience hallucinations, delusions, and psychosis. Other effects include dry mouth, conjunctival injection, tachycardia, and urinary retention. Compared with other hallucinogens, the

effects of marijuana are usually mild and self-limited and require minimal medical intervention.

### Hallucinogens

Hallucinogens are substances that principally alter perception, thought, and mood. This section examines 3 common hallucinogens: lysergic acid diethylamide (LSD), phencyclidine (or phenylcyclohexylpiperidine, [PCP]), and ketamine.

**LYSERGIC ACID DIETHYLAMIDE.** LSD was first synthesized in 1938 from ergot alkaloids extracted from the plant *Claviceps purpurea*. In the 1950s, LSD was used to facilitate psychotherapy, and by the 1960s, it had become a popular recreational drug. LSD is available in several forms, including liquid-impregnated blotter paper, microdots, tiny tablets, windowpane gelatin squares, liquid, powder, and tablets. LSD is usually ingested and has rapid GI absorption.

LSD's psychedellic effects include existential experiences, intensified perceptions, hallucinations, and paranoia. Clinical signs of LSD intoxication include tachycardia, palpitations, blurred vision, tremors, incoordination, and mydriasis. These effects are most intense in the early part of the intoxication. LSD users may experience flashbacks during which an individual re-experiences aspects of the acute intoxication. These episodes are typically short lived and self-limited but may provoke anxiety.

**PHENCYCLIDINE AND KETAMINE.** PCP was commercially available in the 1950s as an anesthetic and re-emerged as a recreational drug in the 1960s. PCP can be used orally or intravenously, smoked, or inhaled. Ketamine is a derivative of PCP and is used medically as a dissociative anesthetic. Ketamine is also a popular recreational agent because of its short duration, low cost, and hallucinatory effects. Recreational ketamine is typically diverted from medical, dental, and veterinary sources and is administered orally, intramuscularly, and intravenously.

PCP blocks the N-methyl-D-aspartic acid receptor to produce its dissociative and psychotic effects. PCP also produces sympathomimetic effects by blocking the reuptake of dopamine and norepinephrine. The clinical effects of PCP can last up to 48 hours after a large dose is ingested. Ketamine is pharmacologically similar to PCP but differs with respect to pharmacokinetics. Intoxication will typically last for approximately 8 hours after oral exposure and 90 to 120 minutes after intramuscular or nasal exposure.

PCP and ketamine cause a dissociative psychotic reaction manifesting as changes in body image and feelings of spiritual separation from the body. Users may have difficulty seeing themselves as separate from their environment. PCP users may experience dangerous or violent behavior, and the emotional state created by PCP is frequently unpleasant. Physical signs of PCP and ketamine intoxication include nystagmus, ataxia, sensory impairment, catatonia, tachycardia, hypertension, and increased secretions. Ketamine intoxication is usually less severe and shorter lived than PCP intoxication. Both ketamine and PCP also have sympathomimetic effects.

Supportive care in a quiet environment with minimal loud or noxious stimuli is usually all that is needed, although verbal and physical contact with friends or family members may be helpful. When agitated, patients should be sedated with appropriate doses of benzodiazepines. Prolonged or severe psychosis will require psychiatric evaluation.

### Stimulants

Cocaine, amphetamine, and related compounds are the most commonly used stimulants. All the stimulants have sympathomimetic effects.

Cocaine is a short-acting stimulant with local anesthetic properties. It is extracted from the leaves of the *Erythroxylum coca* plant. Cocaine can be insufflated (snorted), smoked, or injected. Crack is a purified alkaloid form of cocaine that vaporizes instead of burning, allowing it to be smoked. *Freebasing* describes a technique of heating a cocaine solution until it vaporizes and then inhaling the fumes.

When smoked or used intravenously, cocaine effects begin almost immediately and peak within several minutes. With nasal use, effects begin in a few minutes and peak after 30 minutes. Cocaine is rapidly metabolized to benzoylecgonine and ecgonine methyl ester. These inactive metabolites have a half-life of 4 to 6 hours and can be detected in a urine drug screen up to 48 hours after single use and longer after chronic use. Cocaine interferes with the reuptake of adrenergic neurotransmitters and causes CNS stimulation, vasoconstriction, and blockade of fast sodium channels in axons and in myocardial tissue.

$\alpha$ -Methylphenylethylamine and its derivatives are generically referred to as *amphetamines*. Although amphetamines have been used to treat narcolepsy, asthma, and obesity, their primary current medical indication is for treatment of attention-deficit/hyperactivity disorder (eg, methylphenidate). Methylene-dioxymethamphetamine (MDMA) is an amphetamine derivative commonly known as *ecstasy*, a popular club drug that is used at raves and rock concerts. MDMA stimulates feelings of enhanced emotion and arousal, and hallucinations can occur at high doses.

Amphetamines stimulate the release of dopamine and norepinephrine to cause altered perception, stereotypical and psychotic behaviors, and locomotor stimulation. MDMA stimulates serotonin release and inhibits serotonin synthesis and reuptake. Acute ingestion causes a functional increase in the serotonin concentration; with chronic use, however, serotonin stores are depleted.

The clinical effects associated with these agents are related to stimulation of the CNS and cardiovascular system. Severe effects include seizures and intracranial hemorrhage. The cardiac toxicity of stimulants can cause tachycardia, hypertension, myocardial ischemia, and dysrhythmias. The specific sequelae of cocaine use include endocarditis, pneumothorax, and tactile hallucinations. Amphetamines have been reported to cause choreoathetoid movements and compulsive behaviors. MDMA can cause hyponatremia resulting from the intake of large volumes of water combined with the release of alcohol dehydrogenase.

The treatment of stimulant intoxication requires good supportive care. Benzodiazepine sedation is the most effective treatment for agitation, chest pain, hypertension, hyperthermia, and seizures. Rhabdomyolysis is a common complication of stimulant use and may require aggressive intravenous hydration, urinary alkalization, and rarely hemodialysis. Hyperthermia requires aggressive cooling.

Patients who respond appropriately to sedation and remain asymptomatic for a 4- to 6-hour period of observation generally do not need further medical evaluation.

Cocaine-associated chest pain is an issue of concern. Although most cocaine-related chest pain is short lived and benign, approximately 6% of patients will have an acute myocardial infarction. Most cases occur in the absence of underlying heart disease and can occur in adolescents. The management of myocardial ischemia and dysrhythmias may require the use of benzodiazepines, nitroglycerin, phentolamine, aspirin, morphine, and CCBs. Wide-complex tachycardias associated with cocaine may respond to the use of bicarbonate.

If patients display any persistent signs of cardiac involvement (eg, chest pain, ECG changes, abnormal cardiac enzymes), then they should be admitted to a chest pain observation unit. If patients have normal levels of troponin I, no new ischemic ECG changes, and no cardiovascular complications during a 12-hour observation period, then they generally do not need further medical evaluation.

### Novel Psychoactive Agents

Several psychoactive agents have become more popular during the 1990s and early 2000s. As a group, these agents are often referred to together as “novel” or “new” psychoactive agents (NPS). They are sometimes referred to as “designer drugs” because the chemical structures are often chosen or modified to circumvent legal regulations and changes in the US Drug Enforcement Agency (DEA) scheduling of specific agents. The true chemical constituents of any particular street product can change; when the DEA moves a specific agent to Schedule I status, illicit drug producers try to create a derivative product that is sufficiently different so as to remain unscheduled and that may still technically be legal. Another method of trying to circumvent regulations is to market these substances as bath salts, potpourri, or plant food “not for human consumption.” In this regard, a particular agent may not be scheduled and is marketed as a “legal high.” Although these “novel” agents are structurally diverse, they mimic the stimulant drugs in many of their effects. Polysubstance use is common among users; these novel substances are often used along with one or more other psychoactive substances or alcohol.

**SYNTHETIC CANNABINOID AGONISTS (“K2,” “SPICE”).** Synthetic cannabinoid agonists (SCAs) are not closely structurally related to THC, the active component in marijuana, but they do stimulate both the CB1 and CB2 cannabinoid receptors and were developed specifically to study cannabinoid receptor physiology. Because of their cannabinomimetic activity SCAs have been referred to as “synthetic marijuana.” Sometimes the research-grade chemicals are added to

or sprayed onto mixtures of other plant materials, and these combinations may be referred to as “herbal marijuana alternatives.” The products are typically sold as incense or potpourri and labeled “not for human consumption.” K2 and Spice were specific product names, but the SCA group overall is colloquially referred to as K2 or Spice. Again, the constituents of any particular product are not necessarily specific and are subject to change.

The plant components are typically rolled into cigarettes and smoked like marijuana. Because there are a large number of different compounds within the SCA group, because testing for the specific agents is not generally available, and because the possible toxicity of the other components is largely unknown, attribution of particular clinical effects to specific agents is difficult. In only a small number of cases have the specific agents been identified. Nonetheless, the clinical effects of these agents are becoming better known through the publication of more case reports and case series and have been reviewed. The predominant effects are tachycardia, diaphoresis, dry mouth, and conjunctival injection. More significant effects include agitation, anxiety, paranoia, delusions, psychosis, and suicide. Rhabdomyolysis, respiratory failure, renal failure, myocardial infarction, and death have also been reported. There are no specific antidotes, and treatment is generally supportive and follows the recommendations for the stimulants as described previously.

### SYNTHETIC CATHINONES (“BATH SALTS”).

Cathinone is a naturally occurring amphetamine analog found in the Khat plant (*Catha edulis*). The plant is native to parts of the Middle East and Africa; local populations chew the leaves of the plant for the stimulant effect. Synthetic cathinones are referred to colloquially as “bath salts,” a term that was meant to mask their use as psychoactive agents and circumvent drug regulations. Among the multiple synthetic analogs, the 3 most common derivatives are mephedrone, methylenedioxypyrovalerone (MDPV), and methylone. The antidepressant bupropion is the only synthetic cathinone used medically.

Pharmacologically, the cathinones interact with the transporters of the monoamine neurotransmitters dopamine, norepinephrine, and serotonin, and individual agents will either increase or decrease transmitter concentrations in the synaptic cleft. Overall, the effects of the synthetic cathinones are sympathomimetic. Users report increased energy, empathy, and libido. Adverse effects include nausea, vomiting, headache, hyperthermia, agitation, seizures, and psychosis. Chest pain and palpitations are often the reason for emergency evaluation. Hyponatremia similar to that seen with MDMA has also been reported in several cases. There are no specific antidotes, and treatment is generally supportive and follows the recommendations for the stimulants as described previously.

### 2C-PHENYLETHYLAMINE COMPOUNDS (“NBOME”).

This group of agents includes phenylethylamine derivatives of the 2C class of hallucinogens. The most commonly reported agent is 25C-NBOMe [2-(4-chloro-2,5-dimethoxyphenyl)-N-(2-methoxymethyl)ethanamine]; iodinated and brominated derivatives

are also in circulation. Pharmacologically, this agent is a 5-HT<sub>2A</sub> partial agonist. These agents are used for their hallucinogenic effects and are often sold as or substituted for what a user thinks is LSD. They are typically sold on blotter paper and taken orally or used sublingually. Overall these agents are considered significantly more toxic than LSD.

The desired psychedelic effects include a whole body tingling sensation, euphoria, and auditory and visual hallucinations. Adverse effects include generalized shaking, bruxism, nausea, vomiting, headaches, agitation, tachycardia, hypertension, hyperthermia, agitation, seizures, rhabdomyolysis, and acute lung and kidney injury. Fatalities have been reported related to the use of NBOMe products, particularly 25I-NBOMe. The relative contribution of sympathomimetic versus serotonergic toxicity is unknown, but both are probably contributory. There are no specific antidotes, and treatment is generally supportive and follows the recommendations for the stimulants as described previously. Whether there is a therapeutic role for the use of cyproheptadine, a 5-HT<sub>2A</sub> antagonist, is unknown.

### Inhalants

The inhalation of volatile hydrocarbons such as glue, spray paint, or gasoline is a common form of adolescent substance abuse. Typically, patients will *sniff* (inhale directly), *huff* (soak a rag and inhale from it), or *bag* (squirt or spray hydrocarbon in a bag and inhale from the bag or place the bag over the head). The acute presentation and management of inhalant intoxication differs from the hydrocarbon aspiration syndrome described previously. The primary acute effect of hydrocarbon *inhalation* is altered mental status. At high doses, inhalation may cause significant CNS depression, coma, and respiratory depression. Alternatively, when a person covers the head with a bag, the individual may pass out and become asphyxiated.

Halogenated hydrocarbons such as typewriter correction fluid (trichloroethane) or freon are cardiotoxic; these agents sensitize the heart to catecholamines and can cause malignant dysrhythmias. *Sudden sniffing death* occurs when a patient has been using these agents, experiences a catecholamine surge (eg, when running away from police), and develops sudden ventricular fibrillation.

### Sedative-Hypnotic Agents

Sedative-hypnotic agents encompass a diverse group of agents, including benzodiazepines, barbiturates, ethanol, and  $\gamma$ -hydroxybutyrate (GHB).

Benzodiazepines such as diazepam or alprazolam are commonly prescribed anxiolytic agents. Flunitrazepam (Rohypnol, or *roofies*) is an illicit benzodiazepine common in drug-facilitated sexual assault (date rape); its anxiolytic effects are also used to soften the coming-down phase after cocaine or heroin use. Barbiturates such as phenobarbital, thiopental, or pentobarbital are commonly used sedative, anesthetic, or anticonvulsant agents.

Benzodiazepine and barbiturate effects are mediated by GABA, the predominant inhibitory neurotransmitter

in the brain. Enhanced GABA activity leads to increased sedation. Subtle variations in the GABA receptor allow for the variable physiologic effects of these agents (sedation, hypnosis, anxiolysis, amnesia, and muscle relaxation), and at least 2 types of benzodiazepine receptors have been identified.

Ethanol (ethyl alcohol) is commonly used by teens and preteens and is a contributing factor to injuries related to motor vehicle collisions, homicide, fire, drowning, and suicide attempts. At high doses, ethanol intoxication progresses to CNS depression, with coma and death resulting from respiratory suppression. Ethanol is frequently ingested with other drugs. Ethanol's inhibitory effects are the result of enhanced GABA transmission and inhibition of NMDA glutamate receptors.

GHB was introduced as an anesthetic agent and gained popularity with body builders as a reputed facilitator of growth hormone release. In the late 1980s, its illicit use as a sedative agent and for drug-facilitated sexual assault became more common. Sodium oxybate, a prescription form of GHB, is a Schedule III medication prescribed for narcolepsy and other sleep disorders.

GHB is available in either pill or powder form. It crosses the blood-brain barrier and acts on GHB-specific receptors, the function of which are poorly understood but which may involve dopaminergic pathways. GHB receptor activation may cause agitation or sedation, vomiting, bradycardia, hypotension, coma, and seizures.

Sedative-hypnotic agents are usually identified on urine drug screens. Barbiturates may be detected up to 4 days after ingestion, although phenobarbital may be detected in urine up to 4 weeks after ingestion. Benzodiazepines can be detected from 1 to 30 days after ingestion, depending on the individual agent. Blood alcohol concentrations are routinely available. Standard urine drug assays do not screen for GHB.

The hallmark of sedative-hypnotic intoxication is CNS depression with or without respiratory depression. Respiratory depression can be seen with barbiturate intoxication but is unusual after benzodiazepine intoxication alone. Any combination of agents, including ethanol, increases the risk for respiratory depression. Most sedated patients do well with supportive care. Significant CNS and respiratory depression may require urgent endotracheal intubation to ventilate the patient and to protect the patient from aspiration. Medical interventions should be focused on xenobiotic-specific side effects.

Administration of flumazenil, a specific benzodiazepine antagonist (see Table 369-3), is appropriate in the setting of a known benzodiazepine exposure associated with significant CNS depression, respiratory depression, or both. The empirical use of flumazenil to treat respiratory or CNS depression after an overdose with an unknown agent is not suggested. Flumazenil should not be administered to patients with possible chronic benzodiazepine use because of the high risk for inducing withdrawal or after possible TCA exposure because of the possible risk for inducing dysrhythmias.

Patients with suspected sedative-hypnotic intoxication should be admitted to monitor their respiratory and neurologic status. Patients with barbiturate or benzodiazepine intoxication may require a prolonged hospitalization as a result of the prolonged duration of effect. Patients with uncomplicated ethanol ingestion can usually be observed and discharged after observation in an emergency department setting. GHB and flunitrazepam usually have short durations of action and can typically be managed in the emergency department.

### Opioids

Opioid medications such as morphine, meperidine, codeine, hydrocodone, and oxycodone are commonly used analgesic agents. Heroin is primarily used for its psychoactive effects; methadone is prescribed to treat heroin addiction but is also used to treat chronic pain. Different formulations of these agents are available for oral, intravenous, intramuscular, and subcutaneous administration. Many of these agents can also be insufflated or smoked. Intravenous administration (morphine, meperidine, and heroin) leads to rapid onset of effect and carries the highest risk for adverse effects. All opioids bind to specific opioid receptors; Mu (OP<sub>3</sub>) receptors mediate analgesia, euphoria, and respiratory depression.

Several opioid medications are typically found around the home and are commonly abused, including hydrocodone, oxycodone, and dextromethorphan. A liquid formulation of methadone is frequently prescribed, even to adults. This liquid methadone formulation represents a particular hazard for young children in the home who may be unintentionally exposed.

Oxycodone and hydrocodone are opioid medications commonly prescribed for acute and chronic pain control. Wide-scale prescribing and overprescribing have led to the increased availability and recreational use of these agents. Particularly for adolescents these agents are available around the home and therefore do not require illicit purchase. "Pharming" is a term used to describe the recreational use of prescription medications such as oxycodone or hydrocodone. Recently, efforts to restrict the sale and diversion of prescription opioids have actually led to a resurgence in the use of heroin, even among adolescents.

Dextromethorphan is of special interest to pediatric health care providers because it is an over-the-counter product that has significant abuse potential. It is a well known constituent of a number of cough and cold preparations. As the dextro isomer of the codeine analog levorphanol, it is structurally an opioid, although at therapeutic doses it only has activity at the sigma opioid receptor. It is metabolized to dextrophan, an NMDA receptor antagonist, which gives it some dissociative effects similar to ketamine. It also has some peripheral catecholamine reuptake inhibition, which leads to increased sympathomimetic effects. Users can experience CNS stimulant effects such as hallucinations and euphoria or CNS depressant effects such as a decreased level of consciousness, slurred speech, and memory impairment. Other adverse effects include tachycardia, hypertension, respiratory depression, prolonged QT syndrome, seizures, nausea, and vomiting. Occasional deaths have been reported.

The management of opioid intoxication is based on the history of the exposure and the presence of clinical symptoms. The classic opioid toxidrome includes respiratory depression, CNS depression, and miosis (see Box 369-3). A heroin overdose is also associated with pulmonary edema, which is rarely seen with an overdose of other opioids but may be related to withdrawal. Patients with respiratory or CNS depression related to known or presumed opioid intoxication should receive naloxone as described in the previous section on Resuscitation (see Table 369-3). The most recent advance has been to make naloxone available for bystander administration in the hope that early administration by a family member or friend may prevent an inadvertent opioid death. Opioid metabolites are excreted in the urine and can be detected on a urine drug screen up to 4 days after acute use and longer after chronic use.

Patients who are awake and alert after opioid use do not require further medical evaluation. Patients whose status is reversed by a single dose of naloxone should be observed for at least several hours in case of a recurrence of symptoms. Patients with significant opioid symptoms who have received high or multiple doses or a continuous infusion of naloxone require hospitalization.

### Toxic Alcohols

#### Methanol and Ethylene Glycol

Methanol is found in many commercial products, including antifreeze, windshield washing fluid or de-icer, and picnic stove fuel. Ethylene glycol has a sweet taste and is found in antifreeze, inks, pesticides, adhesives, cosmetics, and paints. The metabolites of methanol and ethylene glycol are toxic. Methanol is initially metabolized to formaldehyde via alcohol dehydrogenase and then to formic acid by aldehyde dehydrogenase. Although absorption of methanol after ingestion is rapid, metabolism and symptoms can sometimes be delayed up to 24 hours. Ethylene glycol is metabolized to glycoaldehyde and then to glycolic acid, glyoxylate, and oxalic acid. Oxalic acid can chelate calcium, and calcium oxalate crystals can precipitate within renal tubules.

Methanol intoxication causes nausea, headache, decreased vision with mydriasis, and weakness. Without treatment, these symptoms may progress to blindness, coma, and death. Ethylene glycol intoxication produces neurologic symptoms ranging from drunkenness to coma followed by tachypnea and pulmonary edema. Ethylene glycol toxicity may cause hypocalcemia and acute renal failure with precipitated oxalate crystals.

Both methanol and ethylene glycol cause an increase in serum osmolality and a positive anion gap acidosis. Increased osmolality is related to the concentration of the parent compound in the serum and is present early in the course of intoxication, whereas an elevated anion gap results from the metabolism of the parent compound and therefore occurs later. Thus the osmolal gap, the difference between the calculated and the measured serum osmolality, decreases while the anion gap increases. An increased osmolal gap suggests intoxication with these alcohols but is neither

sensitive or specific. Methanol and ethylene glycol do not cause lactic acidosis or ketonuria.

Antifreeze often contains fluorescein as an additive to help mechanics locate radiator leaks; thus a Wood's lamp examination of the urine for fluorescence is sometimes suggested to help identify the presence of ethylene glycol. However, this test lacks sensitivity.

Because these agents have rapid absorption from the GI tract, gastric decontamination is not generally useful.

For both of these alcohols the toxic cascade begins when the parent compound is metabolized via aldehyde dehydrogenase. Both fomepizole (4-methylpyrazole) and ethanol competitively inhibit alcohol dehydrogenase and prevent the formation of toxic metabolites (see Table 369-3). Because of adverse effects related to the administration of parenteral ethanol, fomepizole is the preferred antidote. It is important to note that if the patient ingested ethanol in addition to methanol or ethylene glycol, the onset of toxicity may be delayed. Folate and folinic acid enhance the metabolism of formic acid and can be used as adjunctive therapy for methanol poisoning. Thiamine and pyridoxine shunt ethylene glycol metabolism toward less toxic metabolites and are adjunctive therapy for ethylene glycol poisoning. Maintaining the pH near normal with sodium bicarbonate will reduce the availability of and enhance the elimination of some of the toxic metabolites.

For patients who are clinically asymptomatic and in whom acidosis has not yet developed or in patients with mild symptoms or acidosis, fomepizole therapy alone is often adequate. In cases with very high levels of the parent compound or metabolites or with severe acidosis, hemodialysis may still be indicated.

### Isopropyl Alcohol (Isopropanol)

Isopropanol is found in common household products such as rubbing alcohol. In some instances, isopropanol is ingested intentionally as a substitute for ethanol. Unmetabolized isopropanol causes clinical toxicity; as little as 20 mL can cause symptoms. It is metabolized to acetone, which is nontoxic and is excreted by the kidneys and the lungs.

GI toxicity causes nausea and vomiting and can progress to hemorrhagic gastritis. CNS findings include ataxia, muscle weakness, areflexia, lethargy, and coma. Patients who ingest isopropanol can develop myocardial depression with tachycardia and hypotension, renal tubular acidosis, and tracheobronchitis. Patients with isopropanol intoxication have increased serum osmolality and ketonuria but do not have metabolic acidosis.

The clinical presentation of patients with isopropanol ingestion is not usually severe and is rarely fatal. These patients require supportive care and symptomatic therapy. In severe cases, hemodialysis may be necessary for persistent hypotension, plasma levels exceeding 400 mg/dL, prolonged coma, or underlying renal or hepatic disease that limits the metabolism and excretion of isopropanol.

Any patient with suspected or confirmed significant toxic alcohol ingestion and any symptomatic patient should be hospitalized. Patients who have no symptoms

and who are treated early have an excellent prognosis. However, patients with seizures, coma, or pH less than 7.20 have a poor prognosis. Patients who are asymptomatic should be observed for 4 to 6 hours. If they remain asymptomatic, they may be discharged or transferred for further psychosocial evaluation as needed.

## ACKNOWLEDGMENT

### Chapter 370

## PSYCHIATRIC EMERGENCIES: SUICIDALITY, AGITATION, PSYCHOSIS, AND DISASTER EXPOSURE

Heather J. Walter, MD, MPH; David R. DeMaso, MD

Pediatricians increasingly face psychiatric emergencies in their daily work. Pediatric physicians are being asked to assess levels of risk in crisis situations and determine if immediate intervention is indicated, and to have systems in place to ensure that mental health evaluations will be completed. This chapter provides a solid foundation for understanding psychiatric emergencies in general, and evidence-based approaches to 4 specific emergency situations—suicidality, acute agitation, acute psychosis, and disaster exposure.

### NATURE AND SCOPE OF PSYCHIATRIC EMERGENCIES

The number of visits for psychiatric problems by children and adolescents to both pediatric primary care and emergency department settings has increased dramatically; such visits now account for up to 25% to 50% of primary care and 5% of emergency department visits. Compared to other pediatric emergency department visits, psychiatric visits are longer, more frequently triaged to urgent evaluation, and more likely result in patient admission or transfer.

Several factors contribute to the apparent increase in psychiatric emergencies. Among these is the high prevalence of youth risk behaviors likely to result in emergency psychiatric evaluation (see Box 370-1). Another factor is the unavailability of mental health services at both ends of the treatment spectrum. Community and outpatient mental health services and inpatient psychiatric beds and lengths of stay have been steadily eroded by dwindling funds and efforts at cost containment by the government and the private sector. Available services are further constrained by the extreme shortage of mental health professionals across disciplines, including child and adolescent psychiatry,

### BOX 370-1 Prevalence of Youth Risk Factors in Psychiatric Emergencies

- 24.7% of students had been in a physical fight 1 or more times
- 5.2% of students carried a weapon on school property
- 6.9% of students had been threatened or injured with a weapon on school property
- 19.6% of students had been bullied on school property
- 7.1% of students were afraid to go to school because of safety concerns
- 17.0% of students had seriously considered attempting suicide
- 8.0% of students had attempted suicide
- 20.8% of students had had 5 or more drinks of alcohol in a row
- 2.2% to 66.2% of students (depending upon the substance) had used potentially intoxicating substances

From *Youth Risk Behavioral Surveillance—United States 2013* ([www.cdc.gov/mmwr/pdf/ss/ss6304.pdf](http://www.cdc.gov/mmwr/pdf/ss/ss6304.pdf))

child psychology, and child-trained clinical social work and mental health counseling, and by a shortage of training in evidenced-based approaches to treatment. As a result, untreated or undertreated children accumulate across the spectrum of care, and predictable crises occur.

The judgment of what constitutes a psychiatric emergency derives from a number of sources, including the perceptions of a caregiver, teacher, public safety officer, primary care physician (PCP), or of the child himself. Rarely does an emergency occur without warning. Almost invariably, the acute event has been preceded by a long period of instability on the part of the child and impaired relationships within the family or community. Indeed, the cause of the emergency may be as likely to involve a change in the ability of individuals in the child's environment to manage the child's distress as to involve a change in the child's pre-existing psychopathology. Accordingly, a child in crisis represents a family and community in crisis.

Adolescents account for a substantial majority of psychiatric emergencies in youths. Data suggest a preponderance of females among emergency visits, perhaps because girls in crisis are more often perceived to have a psychiatric problem, while boys are perceived to have a delinquency problem. Although varying by community, most emergency visits are for suicidal threats or behavior, followed by assaultive, destructive, or otherwise violent behavior. Additional common presenting psychiatric emergencies are anxiety states (often combined with physical complaints or school refusal) and acute mental status changes including intoxication, psychosis, and delirium.

### GENERAL EMERGENCY PSYCHIATRIC ASSESSMENT CONSIDERATIONS

Child psychiatric emergencies are characterized by severe symptoms, functional impairment, significant distress, and a sense of danger and urgency. Because

a child's mental health is highly dependent on the functioning of the family, school, and community in which she lives, any disturbance in the functioning of these systems has the potential to precipitate a crisis. It is, therefore, critical to answer the questions, *Who is concerned about the child?* and *Why now?*

Whether information is obtained in a clinic visit or in a caretaker telephone call, the PCP needs to determine if the problem is sufficiently severe to require emergency assessment. Threats of harm to self or others, severe out-of-control behavior, and acute mental status changes such as psychosis or delirium all require immediate evaluation. Overwhelming caregiver distress, acute change in overall functioning, or significant symptom exacerbation are examples of circumstances warranting urgent (within 48–72 hours), but not necessarily immediate, evaluation. When immediate evaluation is indicated, physicians must have a system in place to obtain an emergency assessment; Figure 370-1 presents an algorithm for accessing this level of care.

## ELEMENTS OF EMERGENCY PSYCHIATRIC ASSESSMENT

The critical elements of an emergency psychiatric assessment are outlined in Box 370-2. Although the requirement to obtain consent for assessment and treatment is generally waived in emergency situations, reasonable attempts should be made to obtain and document consent from the child's legal guardian. State laws vary with regard to the age at which a minor may self-consent to mental health assessment and treatment. Before beginning an assessment, the limits of confidentiality should be reviewed with the youth and his caregivers. Confidentiality of the youth's disclosures to the physician should not be maintained in circumstances in which the youth presents a danger to herself or others. All professionals are required by federal law to report suspected abuse or neglect. The federal Child Abuse Prevention and Treatment Act sets forth broad guidelines for defining child abuse and neglect; states vary regarding whether there must be knowledge of abuse or merely suspicion of abuse to initiate a report. A searchable database of state statutes is available online through the Child Welfare Information Gateway ([www.childwelfare.gov/topics/systemwide/laws-policies/state](http://www.childwelfare.gov/topics/systemwide/laws-policies/state)). Although consent from the child's guardian or older youth may be a prerequisite for exchanging clinical information with collateral informants, the identification of the situation as emergent can supersede confidentiality protections.

The physical setting for the emergency assessment should reflect the severity of the presenting problem. Some presentations (eg, suicidality, assaultiveness, dangerous unmanageable behavior, and acute mental status changes) generally require the full spectrum of evaluative and stabilization services available in the hospital emergency department setting. Other, less urgent presentations may be suitable for assessment in less restrictive settings. In situations where there is imminent risk of substantial harm, the setting should be secluded from other patients and safeguarded by removing any potentially dangerous personal

possessions, clothing, furniture, medical equipment, and medications. Assistance should be readily available in the event of escalating unmanageability.

Obtaining a full and accurate diagnostic picture requires gathering information from diverse sources, including (as relevant) the family; school staff; prior and current treatment providers; representatives from social services, child welfare, and juvenile justice agencies; and public safety officers. At a minimum, the assessment should include an interview of the child and any accompanying adults. If the caregivers are not present, every effort must be made to contact them for inclusion in the assessment.

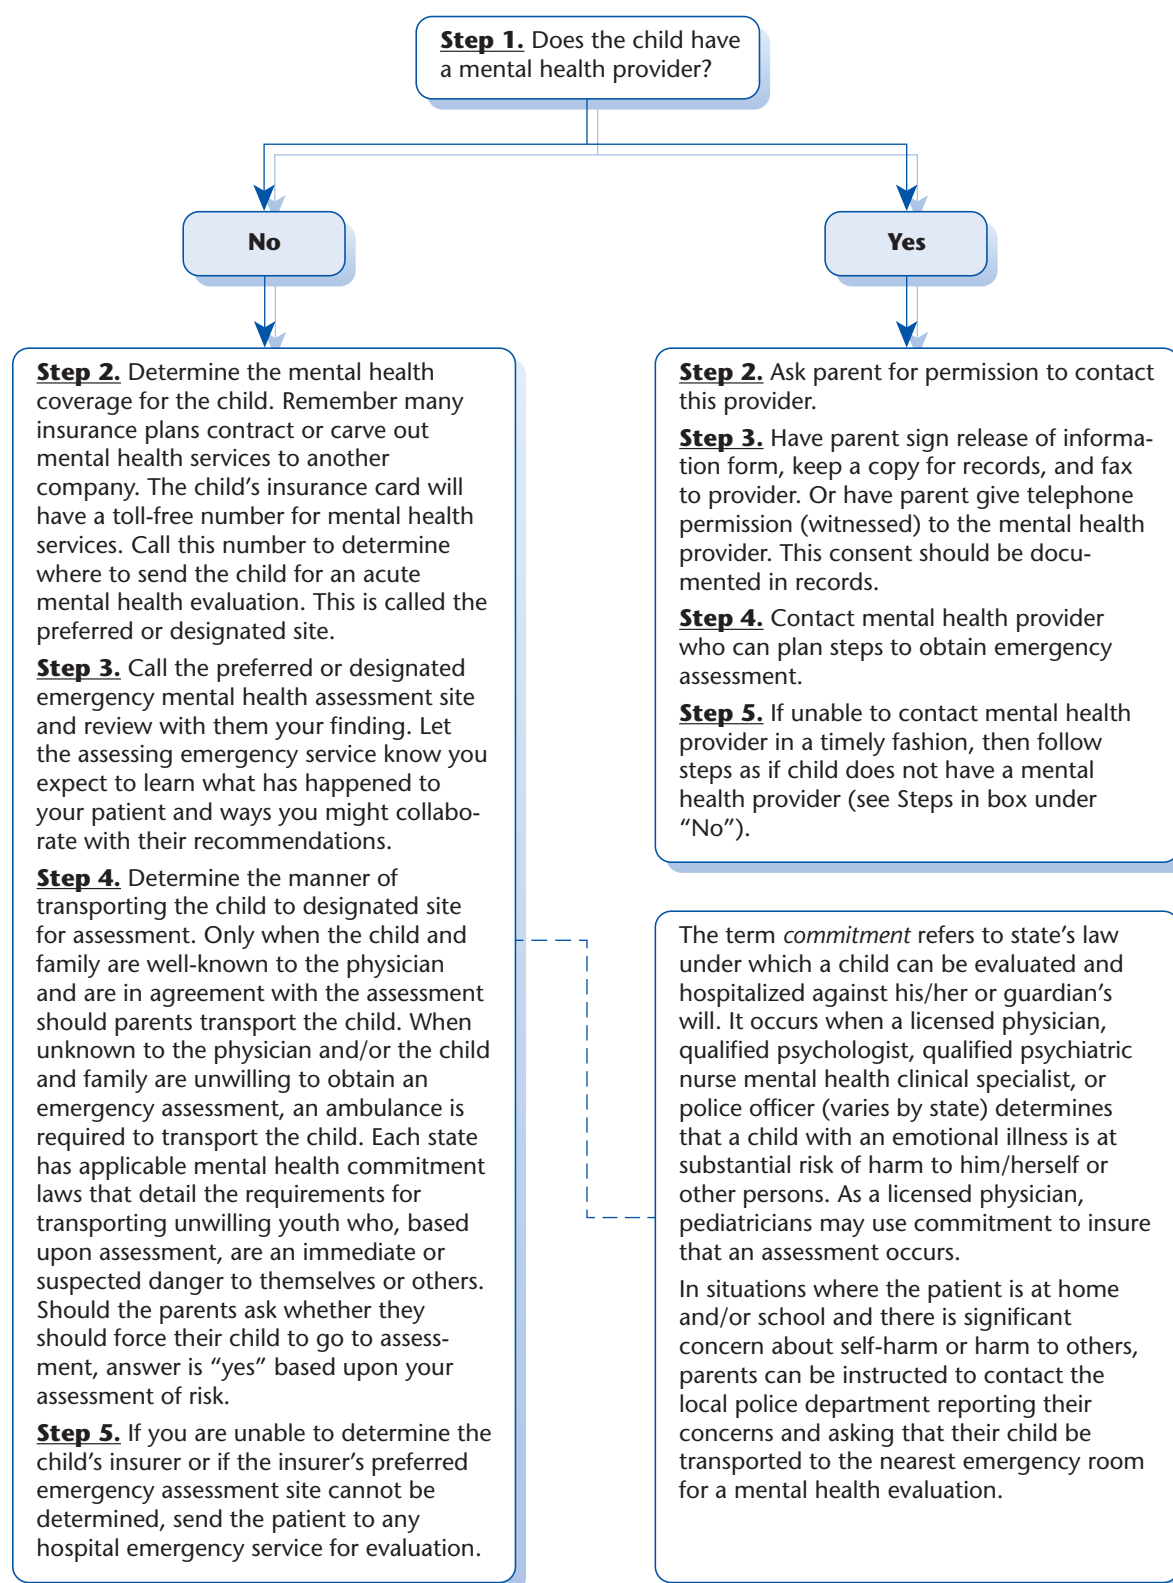

Informants may differ in their access to relevant information. Caregivers or school staff may be quick to report the child's disruptive, aggressive behavior or angry mood, but may be less aware of the child's sadness, worries, or fears. Caregivers may be unaware of how discord within the family system or other traumatic exposure can precipitate a mental health crisis in the child. The interviewer should be aware that vague or sketchy responses to queries, either from the caregivers or the child, or minimization of clear problems can signal a child or family secret, such as physical or sexual abuse, domestic violence, illegal activity, or parental impairment.

In contrast to a routine mental health assessment, in which several sessions may be required to reach a comfort level with the interviewer, an emergency assessment requires that the interviewer gather salient information expeditiously, thereby precluding systematic relationship building. Nonetheless, the interviewer must make every effort to put the child at ease. A useful strategy is to emphasize an interest in the child's perspective of the events leading to the crisis.

The emergency assessment includes a careful physical examination and laboratory tests when indicated by history and physical signs or symptoms, including evidence of a physical illness, prescribed medication use, or substance use that may cause altered mental status.

A key outcome of the emergency assessment is achieving consensus between the caregiver or other referring party and the child on the nature of the presenting problem, its precipitants, and realistic solutions to the problem. Lack of consensus bodes poorly for the success of crisis intervention and disposition plans. Conversely, caregivers/referral sources and children who are able to recognize recurrent patterns and their role in those patterns may be more likely to successfully transition from emergency intervention to treatment, and eventually to health. Caregivers reassuming the care of children after emergency assessment must be capable of adhering to, safeguarding, and monitoring disposition recommendations.

Disposition of the child requires 2 primary decisions—*Does the child present imminent and substantial danger to himself or others?* and *What is the most appropriate level of care?* Empirically derived risk factors for inpatient level of care include suicidal or aggressive presentation, increasing age, presentation during the school year, and substance use by the child or a family member. Disposition decision making is complicated by the constraints of the mental health care delivery

### BOX 370-2 Elements of an Emergency Psychiatric Assessment

- Obtain each informant's account of the crisis from his or her point of view.
- Develop a working alliance with the patient and other involved parties around assessment and disposition.
- Obtain a focused history of the child, including present illness, stressors, psychiatric treatment, and medical, school, developmental, social, and family elements.
- Perform a mental status examination, with close attention to suicidal or homicidal ideation and other mental status abnormalities (eg, hallucinations, delusions, thought disorder, disorientation or confusion, rage, humiliation, anxiety, hopelessness, agitation, impulsivity, impaired communication or cognition, impaired judgment or insight).
- Assess the characteristics of the family relevant to crisis intervention and disposition planning, including the presence of firearms in the home.
- Perform a focused medical assessment as indicated by history and physical signs or symptoms.
- Develop a differential diagnosis, including a formulation of predisposing and precipitating factors.
- Arrive at a judgment of probable danger to self or others.
- Develop and implement a crisis intervention plan.
- Plan and implement an appropriate disposition.
- Communicate assessment findings to relevant parties.

Derived in part from King RA. Practice parameters for the psychiatric assessment of children and adolescents. *J Am Acad Child Adolesc Psychiatry*. 1995;34(10):1386-1402.

and reimbursement systems. In general, there has been a decline in available psychiatry inpatient beds and fewer days of inpatient care for children and adolescents. When children needing a higher level of care are discharged to community or outpatient settings (where there is often a long wait to first visit and between subsequent visits), the stage is set for recurrent crisis presentations.

### SPECIFIC EMERGENT PRESENTATIONS

#### Suicidality

##### Presentation

Suicidality presents on a dimensional spectrum ranging from thoughts about causing intentional self-injury or death (suicidal ideation) to acts that cause intentional self-injury (suicide attempt) or death (completed suicide). The intent to harm oneself, which may be explicit and strong or ambiguous and vague, is the defining characteristic of suicidal behavior, complicated by variations in the construct of intentionality from early childhood to late adolescence. Suicide is rare before puberty. Teenage/young adult American Indian/Alaska Native and non-Hispanic white males have the highest rates of suicide completions, and teenage Hispanic females have the highest rates of suicide attempts. Firearms and ingestion are the most commonly used methods of completing suicide for males and females, respectively. Ingestion is the most commonly used method of attempting suicide. Attempters who have made prior suicide attempts, who used a method other than ingestion, and who still want to die are at increased risk of completed suicide. Table 370-1 outlines several important risk factors for youth suicide.

**Table 370-1** Risk Factors for Youth Suicide

RISK FACTORS	COMMENT
Prior history of a suicide attempt	Increases the risk of suicide nearly 90-fold; strongest predictor.
Psychiatric disorder	~90% of youths who complete suicide have a psychiatric disorder at the time of death, most commonly mood disorders, including major depression and bipolar disorder, followed by substance abuse disorders.
Multiple psychiatric disorders	>70% have multiple psychiatric disorders.
Comorbid mood and substance use disorders	Increase risk of completed suicide nearly 20-fold.
Lack of psychiatric treatment	Large proportion of youths completing suicide had not received treatment.
Personality characteristics	Such as mood instability, impulsiveness, perfectionism, aggression, odd thinking, introversion.
Neurotransmitter dysregulation	Especially serotonergic systems.
Neuroendocrine dysregulation	Especially the hypothalamic-pituitary-adrenal axis.
Disordered sleep architecture	Chronobiological studies suggest a role.
High rates of cumulative stressors	Such as family losses, family discord and dysfunction, parental incapacity, physical or sexual abuse, sexual orientation, immigrant status, living outside the home, not working or attending school, having academic difficulties, bullying, early physical insults (pre-, peri-, postnatal), chronic medical illness.
Social maladjustment	Such as poor interpersonal relationships with family, teachers, or counselors resulting in lack available empathic adults who could offer guidance and support.
Cognitive distortions	Perceived inadequacies, catastrophic thinking, hopelessness. Hopeless feelings in particular impair the youth's ability to manage strong feelings, solve problems, and cope with adversity.

### Evaluation

Assessment of suicidal ideation should be a part of every presentation of a child in crisis, especially those with depressed mood, substance use, or altered mental status. All suicidal ideation and attempts should be taken seriously and require a thorough assessment to evaluate the youth's current state of mind, underlying psychiatric conditions, and ongoing risk of harm. Gathering information from multiple sources and by varied culturally and developmentally sensitive techniques is essential in evaluating suicidal risk factors.

Suicidal ideation can be assessed by a series of questions such as those in Box 370-3. A number of self-report instruments can be helpful in screening for suicidal ideation (see Box 370-4); however, they tend to be oversensitive and underspecific. Using 2 scales with different foci simultaneously (eg, the Suicidal Ideation Questionnaire and the Child-Adolescent Suicidal Potential Index) may provide better coverage of key predictive constructs. All positive results on a screening instrument must be followed by a thorough assessment.

The assessment of suicidal attempts should include a detailed exploration of the hours immediately preceding

the attempt to identify precipitants, as well as the circumstances of the attempt itself to identify intent and potential lethality. A series of relevant topics to address is listed in Box 370-5. Developmental considerations should guide the interview. Thus, young children are susceptible to accidental suicide through imitation or suggestion. Preadolescents may have difficulty with the construct of intentionality. In adolescents, lethality is not necessarily related to the severity of the attempt; youths with serious intent, for example, may think that a small number of over-the-counter analgesic pills can be lethal.

Acute changes in mental status (eg, intoxication, agitation, psychosis, disorientation) increase the risk of suicidality and require physical examination to rule out a medical etiology for the change. Physical examination may provide evidence of physical or sexual abuse, prior suicide attempts, or other self-harm, or a physical illness that could cause altered mental status. Laboratory studies should be considered when suggested by the physical findings (eg, urine toxicology screen or a pregnancy test).

### Management

The assessment of suicidality culminates in answers to 2 basic questions—*Is the patient at current risk for attempted or completed suicide?* and *Are the patient and family able to adhere to recommendations regarding supervision, safeguarding, and follow-up care?* Management should be embedded within the pediatric medical home, where the PCP is informed and aware of the management plan. Follow-up visits in the pediatric setting support mental health management.

Psychiatric hospitalization is indicated when the youth actively voices suicidal intent. Intent can be explicitly stated (“I want to die”) or implied (“I can’t see

#### BOX 370-3 Questions to Elicit Suicidal Ideation/Behavior

- Did you ever feel so sad or upset that you wished you were not alive or wanted to die?
- Have you ever thought that you or your family would be better off if you were dead?
- Did you ever do something that you knew was so dangerous that you could get hurt or killed by doing it?
- Have you ever thought about killing yourself?
- Did you ever try to kill yourself?
- Did you ever try to kill yourself, and not tell anyone?
- Did you ever make a plan to kill yourself? If so, what was the plan?

#### BOX 370-5 Topics to Explore for a Suicide Attempt

- Why was the method chosen?
- What were the expectations from the attempt (did the patient think the attempt was going to kill him)?
- How reversible was the attempt?
- Did the circumstances permit the patient to change her mind about the attempt?
- Does the patient demonstrate ambivalence about living?
- How strong was the patient's intent to die?
- Was there evidence of premeditation, including preparations and precautions against discovery?
- Did the patient tell anyone about the attempt, particularly responsible caretakers?
- What did the patient do immediately after the attempt?
- Did the patient seek help or simply disregard the danger of the attempt?
- Did the patient acknowledge the attempt or try to hide or deny the attempt?
- Is the patient relieved or disappointed that he survived the attempt?

any reason to go on living"). These youths typically have frequent thoughts about suicide that occur over long periods of time. They describe specific plans that are not only well conceived and potentially lethal, but also feasible in their environment. Concern is heightened if the youth has known risk factors for suicidality (especially a previous attempt, untreated depression, or substance use), or if the youth is aware of another youth (with whom he can identify) or a family member who has completed suicide. Medical hospitalization may follow a suicide attempt, and when the youth is medically stable, but remains potentially dangerous, a transfer to a psychiatric facility should be arranged.

Hospitalization also is indicated in the context of altered mental status, a history of psychiatric disorder unsuccessfully treated in outpatient or day-hospital settings, active substance use, and caregiver incapacity. Caregivers of suicidal youths must believe that their relationship with their child is sufficiently close that their child will disclose suicidal thoughts should they occur in the future. Caregivers must be able to supervise the child closely during the acute phase of assessment and treatment, to safeguard the home by removing access to potentially lethal methods of suicide (eg, firearms, prescribed and over-the-counter medications), and to adhere to all follow-up assessment and treatment recommendations.

The primary goal of hospitalization is to keep the child safe from self-harm. Other goals are to clarify psychiatric diagnoses and develop a comprehensive treatment plan with individual, family, and environmental (eg, school and community) interventions. Pharmacotherapy may be initiated in the presence of moderate to severe psychopathology. Youths typically remain hospitalized until active intent to die has abated, and a safe and secure discharge plan to which caregivers can adhere is in place.

A referral for psychiatric outpatient follow-up may be appropriate if the youth has suicidal ideation without intent or plan; has an intact mental status; has few to no other risk factors for suicidality; is willing and able to participate in outpatient treatment; and has caregivers able to provide emotional support, supervision, safeguarding, and adherence to follow-up. Other considerations are systems related, including the availability of urgent outpatient appointments, qualified

mental health providers, and evidence-based treatment modalities.

PCPs should be aware that the rate of completed psychiatric outpatient referrals is known to be very poor. Moreover, approximately one-third of referred youths attend only 1 or 2 sessions, and one-quarter appear only 3 or 4 times. Several factors influence likelihood of follow through, including a history of previous hospitalization, severe symptoms of psychiatric disorders, and the lethality of the attempt. PCPs can help educate the patient and family about the causes and treatment of suicidality, and the risks of failing to treat. The likelihood of a completed referral also can be increased by making sure that the family secures a specific appointment day and time at the time of the emergency psychiatric assessment.

The goals of psychiatric outpatient treatment are to successfully treat the underlying psychiatric disorders and to prevent further suicidality. Optimal treatment will consist of evidence-based approaches, including individual psychotherapy and pharmacotherapy, family therapy, and group therapy. Although no specific treatment modalities have been shown in rigorous studies to prevent suicidality, several psychotherapies have been shown to be promising, including dialectical behavioral therapy and cognitive behavioral therapy–suicide prevention (see Table 370-2).

If the psychiatric disorder underlying suicidality is depression, antidepressant medication can be considered as part of a comprehensive treatment plan. In a pilot study among adolescent suicide attempters with depression, combination treatment (antidepressant medication and cognitive behavioral therapy) resulted in improvements in depressive symptoms similar to those demonstrated in other studies among nonsuicidal depressed adolescents. Physicians must be aware of the association between antidepressant medications and suicidal thoughts, and the need to closely monitor patients who are prescribed these medications.

### Acute Agitation Presentation

Acute agitation encompasses a psychological state (feeling of inner tension or arousal) as well as a motoric state (pacing, hand wringing, fidgeting). It can occur in the context of a number of psychiatric,

**Table 370-2** Psychotherapies for Suicidality

PSYCHOTHERAPY TYPE	DESCRIPTION
Dialectical behavioral therapy	Designed for individuals with deficits in emotional regulation; focus is both on mindfulness and acceptance (derived from Asian philosophy) and on skills building (derived from cognitive behavioral therapy). Uses 4 skills modules to address emotion regulation, interpersonal effectiveness, mindfulness, and distress tolerance.
Cognitive behavioral therapy–suicide prevention	Designed for youths who have made a suicide attempt; detailed chain analysis identifies proximal risk factors (eg, emotional, cognitive, behavioral, and family) active just before and after the attempt. These factors include deficits in the youth's ability to regulate emotions, resolve problems, tolerate distress, and address negative thoughts such as worthlessness or hopelessness. A core feature of the treatment is the development of an individualized case conceptualization that identifies problem areas to be targeted and specific interventions to be used during periods of acute emotional distress.

general medical, and substance-induced conditions, as outlined in Box 370-6. The critical first step is to determine whether the acute agitation is because of a general medical condition, substance- or medication-induced condition, or primary psychiatric disorder.

Acute agitation in a general medical or substance/medication-induced condition is characterized by disturbances in consciousness (reduced clarity of awareness of environment) and changes in cognition over a short period of time. Consistent with the diagnosis of delirium, this type of agitation is often accompanied by cognitive changes (eg, memory deficit, disorientation, inattention, language disturbance), mood changes (eg, irritability), and perceptual disturbances (eg, acute illusions, hallucinations, or delusions). In contrast, agitation in primary psychiatric disorders generally is not accompanied by the acute disturbances in consciousness or cognition. Agitation in autism spectrum disorder can be associated with underlying physical illnesses that cannot be readily communicated by the patient to others, or to environmental changes that unsettle the needed consistent daily routines.

### **BOX 370-6 Disorders Commonly Associated With Agitation**

#### **General Medical Conditions**

- Delirium related to direct effect of physical illness
- Acute drug intoxication

#### **Psychiatric Disorders**

- **Neurodevelopmental disorders**
  - Intellectual disability
  - Autism spectrum disorder
  - Attention-deficit/hyperactivity disorder
- **Disruptive, impulse control, and conduct disorders**
  - Oppositional defiant disorder
  - Intermittent explosive disorder
  - Conduct disorder
- **Anxiety disorders**
  - Separation anxiety disorder
  - Panic disorder
  - Generalized anxiety disorder
- **Depressive and bipolar**
  - Major depressive disorder
  - Bipolar disorder
  - Disruptive mood dysregulation disorder
- **Obsessive-compulsive disorder**
- **Trauma- and stressor-related disorders**
  - Post-traumatic stress disorder
  - Acute stress disorder
- **Psychotic disorders**
  - Schizophrenia
  - Other psychotic disorders
- **Substance-related disorders**
  - Intoxication or withdrawal states

**Parent-child relational problem**  
**Abuse and neglect**

### **Evaluation**

An acutely agitated child must be thoroughly assessed for underlying medical, medication, or substance use causes using physical examination and laboratory and imaging tests as indicated (Box 370-7). This process must be completed before assuming a psychiatric cause for a patient's agitation. In the case of suspected delirium, serial assessments are required because of the fluctuating nature of the disorder. Various instruments are used to diagnose delirium and assess symptom severity. Among the most widely used instruments for youths is the Delirium Rating Scale, which has versions for younger and older children. Table 370-3 outlines the differential diagnosis of pediatric delirium using the mnemonic "I WATCH DEATH."

### **Management**

For all cases of agitation, the most effective treatment addresses the underlying cause. In the interim, the physician treats the acute agitation to ease the distress of the patient and family, reduce the potential for unintentional harm, and improve the medical outcome (if relevant). Box 370-8 outlines nonpharmacologic approaches for the physician facing a child or adolescent with acute agitation. If these initial interventions are ineffective, physicians should consider the use of pharmacologic interventions or seclusion or restraint if necessary to prevent harm to self or others. States vary in their regulations on the use of emergency pharmacologic interventions and seclusion or restraint for out-of-control behavior. Box 370-9 presents considerations for the assessment of children for emergency medication treatment, and Box 370-10 presents national guidelines for the use of seclusion and restraint.

Special treatment considerations pertain to the child with delirium. Environmental intervention is particularly important. Frequent and repeated reassurance

### **BOX 370-7 Selected Tests to Be Considered for the Medical Evaluation of Agitation**

#### **HEMATOLOGY**

Complete blood count

#### **CHEMISTRY**

Electrolytes, glucose, blood urea nitrogen, creatinine, total protein, liver function tests, calcium, magnesium, phosphorus, thyroid function tests, kidney function tests

#### **OTHER LABORATORY**

Pregnancy, heavy metals, B<sub>12</sub>, folate, lupus prep, antinuclear antibodies, urine porphyrins, ammonia, erythrocyte sedimentation rate, human immunodeficiency virus, urine toxicology screen, serum drug levels, arterial blood gases, electrocardiogram

#### **IMAGING**

Chest radiograph, computed tomography, magnetic resonance imaging, echocardiography, endoscopy

#### **OTHER**

Electroencephalogram, electrocardiogram, lumbar puncture

From Wise MG, Brandt G. Delirium. In: *The American Psychiatric Press Textbook of Neuropsychiatry*. 2nd ed. Hales RE, Yudofsky SC, eds. Washington, DC: American Psychiatric Press; 1992:302. Copyright © 1992, American Psychiatric Press, Inc. Used with permission.

**BOX 370-8 Nonpharmacologic Approaches to the Child or Adolescent with Acute Agitation****EDUCATE**

- Explain to the patient and caretaker your understanding of the cause of the acute agitation and that it is a time-limited consequence of an underlying disorder.
- Because of interference with cognitive ability, explanations or statements to the patient should be short, succinct, and focused (eg, “You must calm down . . . we will be giving you medicine to help you stay safe...you can have the medicine by mouth or by injection”).
- Outline the needed intervention, which may include physical and medication restraints. Explain that this is an emergency situation that will require intervention to protect the patient as well as others.
- If possible, obtain consent from the caretaker regarding the intervention plan.

**CALMING INTERVENTIONS**

- If you are feeling alarmed, this is an indication that patient is “out of control.”
- Do not take anger personally, but do take into consideration your own safety.
- Clearly introduce yourself to patient.
- Use simplified language, soft voice, and slow movements.
- Explain what will happen in the outpatient setting, the emergency department, or the medical/surgical floor.
- Reassure the patient that you are there to keep him safe.
- Have someone familiar provide frequent, repeated reassurance and reorientation to help decrease fear and confusion.
- Do not leave the patient alone; instead, the patient should remain in the company of a family member or clinical staff.
- Tell the patient how you plan to honor her reasonable requests.
- Understand the patient’s goal, and link cooperation to the goal.
- Offer food or drink.
- Reduce environmental stimulation (eg, reduce lighting and number of people).
- Remove access to breakable objects or equipment.
- Find things for the patient to control.
- If appropriate, offer distracting toys or sensory modalities.
- Limiting staff changes and involving relatives in care often eliminates the need for medication.
- If the patient does not respond to verbal reassurance, it may be necessary to provide a “show of force” to convey a message to the patient that external control will be placed on his behavior to protect him as well as others. Hospital security staff or police in the community can effectively deter acting-out behaviors simply by being visible in sufficient numbers.

### BOX 370-9 Considerations in Assessment of Children for Emergency Medication Treatment

1. Benefits of treatment and risks of withholding treatment.
2. Benefits and potential risks of proposed medication.
3. Route of medication administration: Is oral administration possible? If not, does the patient have alternative routes already in place such as intravenous access or a gastric tube, or would the medication have to be administered rectally or intramuscularly and potentially be more traumatic?
4. Necessity of physical restraint to administer medication.
5. Patient age: A mature minor may be able to consent to treatment. Efforts should be made to document that the physician has communicated with the patient before giving the medication. The younger the child, the less input she will have regarding treatment.
6. Level of anxiety: A mild panic attack episode characterized by hyperventilation and tremors may not require any immediate intervention, whereas a severe attack associated with acute agitation (eg, pulling out intravenous or nasogastric tubes or removing an oxygen mask) constitutes a higher level of urgency.
7. Level of agitation: A mild episode characterized by restlessness may not require any immediate intervention, whereas severe agitation associated with significant threat of harm to others would constitute a higher level of urgency.

From Ibeziako P, Bourne R, Shaw RJ, DeMaso DR. Legal and forensic issues. In: Shaw RJ, DeMaso DR, eds. *Textbook of Pediatric Psychosomatic Medicine: Mental Health Consultation with Physically Ill Children*. Washington, DC: American Psychiatric Press, Inc; 2010:47–62. Copyright © 2010, American Psychiatric Press. Used with permission.

and reorientation by someone familiar helps to decrease fear and confusion. Limiting staff changes, providing a safe and uncluttered environment, but with orienting objects (eg, clocks, calendars, pictures of family and home, familiar objects from home), minimizing excess ambient noise, and providing good day lighting and low night lighting all facilitate orientation. If pharmacologic interventions are needed to maintain safety, antipsychotic medications can be very beneficial for the agitated patient with perceptual disturbances, sleep-wake cycle abnormalities, and behavioral dyscontrol. Haloperidol has been favored because it has few metabolites, a safe parenteral form, few anticholinergic and hypotensive side effects, and relatively less sedation than other agents. The intravenous route should be considered if rapid acute control of agitation is required. Care should be taken to monitor anticholinergic (eg, acute dystonia) and cardiac (eg, prolongation of the QTc interval) side effects.

Agitation derived from causes other than delirium can be treated with medication according to guidelines presented in Table 370-4 and Box 370-11.

### Acute Psychosis

#### Presentation

Psychotic symptoms include delusions, hallucinations, disorganized thinking (as manifested in disorganized

### BOX 370-10 Guidelines for the Use of Seclusion and Restraint for Children and Adolescents

1. Restraint or seclusion must only be used when it can be clinically justified or when warranted by patient behavior that threatens the physical safety of the patient, staff, or others.
2. A physician or clinical psychologist, or other authorized licensed practitioner (physician) primarily responsible for the patient's ongoing care orders the use of restraint or seclusion in a manner consistent with hospital policy.
3. The physician is consulted as soon as possible if he or she did not order the restraint or seclusion.
4. The physician primarily responsible for the patient's ongoing care conducts an in-person evaluation of the patient within 1 hour of initiation.
5. The in-person evaluation by the physician includes an evaluation of the patient's immediate situation, the patient's reaction to the intervention, the patient's medical and behavioral condition, and the need to continue or terminate the restraint or seclusion.
6. Orders are time limited and may be renewed within 2 hours for children and adolescents aged 9–17 years, and within 1 hour for children under age 9 years, for a maximum of 24 consecutive hours.
7. At least every 24 hours, the physician must evaluate the patient before writing a new order for restraint or seclusion.
8. Patients in seclusion or restraint must be continuously monitored.
9. Seclusion and restraint must be documented in the patient's medical record in a manner consistent with hospital policy.

Adapted with permission from 2016 *Comprehensive Accreditation Manual for Hospitals*. Oakbrook Terrace, IL: Joint Commission Resources; 2015.

speech), disorganized behavior, and “negative” symptoms (eg, diminished emotional expressiveness, decreased motivation). Hallucinations can be auditory, visual, tactile, olfactory, or gustatory, and occur in the absence of identifiable external stimuli.

#### Evaluation

New-onset psychotic psychiatric disorders are uncommon before adolescence; psychotic symptoms occur more commonly in the context of an underlying medical illness or substance-related conditions. The differential diagnosis of medical causes of acute psychosis is broad (Box 370-12). As with the evaluation of acute agitation, a thorough history and physical examination are crucial investigatory tools, and laboratory and radiologic workup can narrow the differential (see Box 370-7).

If a medical cause for acute psychosis can be ruled out, psychiatric etiologies can be considered. The differential diagnosis comprises a broad range of psychiatric disorders, including diagnoses in which hallucinations are not the hallmark feature but may be viewed as associated symptoms (eg, post-traumatic

Table 370-4

## Psychotropic Medication Management of Acute Agitation in Children and Adolescents

## MEDICATION CONSIDERATIONS FOR MILD AGITATION

- Mild agitation can be defined as excessive worries or fears that respond to calming interventions; physician feels in control; patient agrees to take medication.

PARAMETER	CHILD (8–12 YEARS)	ADOLESCENT (≥13 YEARS)
Preferred agent(s)	Lorazepam <b>or</b> standing antipsychotic <sup>a</sup>	Lorazepam <b>or</b> standing antipsychotic <sup>a</sup>
Administration route	By mouth	By mouth
Initial dosing	Lorazepam 0.5–1 mg	Lorazepam 1–2 mg
Initial endpoint	Calm/cooperative	Calm/cooperative
Assessment frequency	q15min until calm	q15min until calm
Redosing frequency	Lorazepam q2hrs	Lorazepam q2hr
Time to maximum plasma concentration	Lorazepam 2 hr	Lorazepam 2 hr

## MEDICATION CONSIDERATIONS FOR MODERATE AGITATION

- Moderate agitation can be defined as verbal aggression; patient does not respond to interventions; physician feels worried; patient agrees to take medication.

PARAMETER	CHILD (8–12 YEARS)	ADOLESCENT (≥13 YEARS)
Preferred agent(s)	Risperidone <sup>c</sup> <b>or</b> haloperidol <sup>d</sup>	Risperidone <sup>c</sup> <b>or</b> haloperidol <sup>d</sup>
Administration route	By mouth	By mouth
Initial dosing	Risperidone 0.25–0.5 mg <b>or</b> haloperidol 2 mg	Risperidone 0.5–1 mg <b>or</b> haloperidol 5 mg
Initial endpoint	Calm/cooperative	Calm/cooperative
Assessment frequency	q15min until calm	q15min until calm
Redosing frequency	Haloperidol q4–8hr Risperidone q12hr	Haloperidol q4–8hr Risperidone q12hr
Time to maximum plasma concentration	Haloperidol 2–4 hr Risperidone 1 hr	Haloperidol 2–4 hr Risperidone 1 hr

## MEDICATION CONSIDERATIONS FOR SEVERE AGITATION

- Severe agitation can be defined as physical aggression or destruction of property; explosive situation; physician feels alarmed; patient refuses medication.

PARAMETER	CHILD (8–12 YEARS)	ADOLESCENT (≥13 YEARS)
Preferred agent(s)	Haloperidol <sup>f</sup> alone <b>or</b> haloperidol <b>and</b> lorazepam together <sup>g</sup>	Haloperidol <sup>f</sup> alone <b>or</b> haloperidol <sup>f</sup> <b>and</b> lorazepam together <sup>g</sup>
Administration route	Intramuscular	Intramuscular
Initial dosing	Haloperidol 2 mg <b>or</b> haloperidol 2 mg and lorazepam 0.5–1 mg	Haloperidol 5 mg <b>or</b> haloperidol 5 mg and lorazepam 1–2 mg
Initial endpoint	Calm/cooperative	Calm/cooperative
Assessment frequency	q15min until calm	q15min until calm
Dosing frequency	Haloperidol q4–8hr	Haloperidol q4–8hr
Time to maximum plasma concentration	Haloperidol: 30 min; lorazepam: 10 min	Haloperidol: 30 min; lorazepam: 10 min

## IF NO ORAL OR INTRAMUSCULAR ACCESS—MEDICATION CONSIDERATIONS

- Patients can present with agitated states in the pediatric hospital setting where there is *no access by mouth and intramuscular is contraindicated* (eg, muscle wasting). In these situations, acute control is required given the endangering nature of the agitation (eg, pulling tubes).

Continued

**Table 370-4 Psychotropic Medication Management of Acute Agitation in Children and Adolescents—cont'd**

PARAMETER	CHILD (8–12 YEARS)	ADOLESCENT (≥13 YEARS)
Preferred agent(s)	Haloperidol <sup>h</sup>	Haloperidol <sup>h</sup>
Administration route	Intravenous	Intravenous
Initial dosing	Haloperidol 0.5–1 mg	Haloperidol 1–2.5 mg
Initial endpoint	Calm/cooperative	Calm/cooperative
Assessment frequency	q5–10min until calm	q5–10min until calm
Dosing frequency	q30min when necessary	q60min when necessary
Time to maximum plasma concentration	10 min	10 min

<sup>a</sup>If already on a standing antipsychotic, consider an additional ¼ to ½ of the usual dose.

<sup>b</sup>Consider clonidine 0.05–0.1 mg for patients with standing clonidine or a diagnosis of attention-deficit/hyperactivity disorder, autism spectrum disorder, or disruptive behavior disorders.

<sup>c</sup>For Risperidone, if no response after 30 min, repeat ½ original dose; if no response after 60 min, may give lorazepam (child 0.5–1 mg; adolescent 1–2 mg).

<sup>d</sup>For haloperidol, if no response after 30 min, repeat ½ original dose; if no response after 60 min, may give Diphenhydramine (child 25 mg; adolescent 50 mg). Diphenhydramine also may be given with the initial dose of haloperidol to prevent acute dystonia.

<sup>e</sup>Risperidone is available in liquid formula; haloperidol is available in a liquid concentrate.

<sup>f</sup>For haloperidol, if no response after 30 min, repeat ½ original dose; if no response after 60 min, may give diphenhydramine (child 25 mg; adolescent 50 mg). Diphenhydramine also may be given with the initial dose of haloperidol to prevent acute dystonia.

<sup>g</sup>The combination of haloperidol and lorazepam can be considered when there is *imminent risk of substantial harm to self or others*.

<sup>h</sup>Monitor for prolongation of the QT interval and cardiac arrhythmias.

From *The Patient Care Manual*. Children's Hospital Boston. 2014.

### BOX 370-11 Medication Monitoring Requirements and Administration Considerations

#### MONITORING REQUIREMENTS

- Vital signs and blood pressure along with observation for the development of extrapyramidal side effects (eg, akathisia, dystonic reactions) and respiratory depression.
- Intravenous haloperidol only: ideally, assess QTc at baseline and periodically after administration. Avoid use in patients with known QTc prolongation.

#### ADMINISTRATION CONSIDERATIONS

- Both first-generation (typical) and second-generation (atypical) neuroleptics have evidence supporting their utilization for acute agitation. To date, neither type has been proven superior to the other. Each medication has its own individual side effects, which should be considered for each patient. These medication guidelines are only for acute situations.
- Medication can be given in an emergency situation without parental (or legal guardian) consent when there is danger to self or others.
- Show of force (eg, security or other personnel) when administering medication can be helpful, if medication is resisted by patient.
- Prepare both by mouth and intramuscular formulations so that either can be given.
- Use a time frame (eg, you have 5 minutes to take this medication by mouth; otherwise, we will need to give you the medication as a shot).
- Half-life of diphenhydramine is potentially much shorter (2–9 hours) than that of antipsychotics (haloperidol 12–36 hours, risperidone 24 hours), so if acute dystonia is treated with diphenhydramine, a dose of benzotropine or additional dose of diphenhydramine should be considered within a few hours.

stress disorder [PTSD], nonpsychotic mood disorders, and disruptive behavior disorders); diagnoses that are defined by psychotic features (eg, brief psychotic disorder, schizophrenia, major depression or bipolar disorder with psychotic features); and at-risk clinical states (poor reality testing).

In children with nonpsychotic hallucinations, the symptom cluster of psychosis (delusions, disorganized thoughts and behavior, negative symptoms) is absent. Nonpsychotic hallucinations commonly occur in the context of severe traumatic stress, developmental delays or disorders, social and emotional deprivation, caregivers whose own psychopathology promotes a breakdown in the child's sense of reality, cultural beliefs in mysticism, unresolved mourning, and normal development ("magical thinking").

#### Management

The underlying condition will determine the type of treatment needed. Nonpsychotic hallucinations suggest the need for disorder-specific psychotherapy (eg, trauma-focused cognitive behavioral therapy for PTSD, parent management training for behavior disorders) and perhaps adjunctive medication (eg, an antidepressant for depression or anxiety, or a brief course of antipsychotic medication). Psychotic hallucinations may be an indication for antipsychotic medication. Hallucinations from intoxication or physical illness typically resolve in parallel with the underlying condition.

#### Disaster Exposure Presentation

A disaster is a sudden and severe ecological and psychosocial disruption that greatly exceeds the coping capacity of the community. Children may experience a spectrum of psychological effects across the disaster timeline that vary according to developmental stage (Box 370-13). Transient moderate psychological distress

**BOX 370-12 Differential Diagnosis of Medical Causes of Acute Psychosis****Drugs (prescribed and illicit)****Trauma****Organ failure**

- Cardiopulmonary
- Hypertensive encephalopathy
- Renal azotemia
- Hepatic encephalopathy

**Electrolyte abnormalities****Neurologic**

- Acute rheumatic fever

**Vitamin deficiencies****Anoxia/hypoxia**

may be a normative reaction to traumatic exposure. More severe symptoms in the first month may qualify for a diagnosis of acute stress disorder; symptoms persisting longer than 1 month may qualify for a diagnosis of PTSD.

**BOX 370-13 General Trauma Reactions in Children and Adolescents****YOUNGER CHILDREN**

- Clinging and dependent behaviors
- Phobic reactions
- Sleep and appetite disturbances
- Nightmares
- Loss of bladder and bowel control
- Temper tantrums
- Hyperactivity

**OLDER CHILDREN**

- Reenacting the trauma through play
- Sleep and appetite disturbances
- Somatic complaints
- Concentration difficulties
- Irritability
- Hyperactivity
- Decline in school performance

**ADOLESCENTS**

- Hyperarousal
- Avoidance
- Numbing
- Anxiety, including panic
- Depressed mood
- Social withdrawal
- Suicidal ideation and behavior
- Flight into pseudoindpendence
- Belligerence
- Risky behaviors (sex, drugs, violence)
- Interpersonal conflict

**Risk Factors**

A number of factors can mediate the effect of disaster exposure on youths. These include the specific nature of the traumatic exposure (eg, type of disaster, intensity, duration, physical proximity, injury, loss of loved ones, loss of possessions, exposure to media coverage); individual factors (eg, age and developmental stage, gender, pre-existing academic function, pre-morbid psychiatric or medical illnesses, post-trauma exposure or grief experiences, adaptive coping skills, resilience, positive emotions); family factors (eg, good parent-child relationships, parental harmony, positive family ambience, extended family support, cultural identification); and community factors (eg, secondary stressors, traumatic reminders, social support, and school and religious affiliations).

Most individuals who experience life-threatening events manifest symptoms immediately. However, only around one-third tend to manifest enduring symptomatology after the first month. Female gender, previous trauma exposure, multiple traumas, greater exposure to the index trauma, presence of a pre-existing psychiatric disorder (particularly an anxiety

### **BOX 370-14 Selected Screening Instruments to Assess Traumatic Exposure**

disorder), parental psychopathology, and lack of social support are risk factors for a child developing PTSD after trauma exposure. Conversely, parental support, lower levels of parental PTSD, and resolution of other parental trauma-related symptoms have been found to predict lower levels of PTSD symptoms in children. Increased television viewing of disaster-related events, delayed evacuation, extreme panic symptoms, or having felt that one's own or a family member's life was in danger have each been found to be independently and significantly associated with the development of PTSD. Untreated PTSD is associated with significant morbidity. Despite some studies showing "natural recovery," other studies have shown that PTSD symptoms in children can persist over many years, affecting function in multiple domains.

#### **Assessment**

Psychological screening of disaster survivors facilitates intervention by identifying those with the greatest need. The appropriate timing of screening remains in debate because of the nearly ubiquitous distress that accompanies disasters. Screening is often conducted in school settings using instruments to assess trauma exposure as well as internalizing and externalizing reactions to the exposure. Examples of such instruments are presented in Box 370-14. A limitation of standardized screening is the wide variety of emotional and behavioral responses to trauma exhibited by children.

For children with clinically significant symptoms, formal clinical assessment should ensue, including a personal interview with the child and caregivers supplemented by information from other sources. The parent interview should clarify the nature, severity, and duration of the child's and family's disaster exposure and experience; identify the inventory of current stressors; examine the spectrum of symptoms in the child; document the child's psychiatric, developmental, school, and family history; and enumerate important contextual mediators. Children should be asked directly about their experience of and reactions to traumatic exposure. In most instances, children are able to recount their experience in words or to use nonverbal means (eg, play, drawing) to relate what occurred. It is important that the interviewer provide

the child with the opportunity to describe his experiences in whatever medium he chooses, and support the child by explaining emotional reactions, cognitive distortions, and maladaptive behaviors.

The diagnosis of both acute stress disorder and PTSD require exposure to actual or threatened death, serious injury, or sexual violation in one of the following ways: directly experiencing the event; witnessing, in person, the event as it occurred to others; learning that the event (which must be violent or accidental) occurred to a close family member or close friend; and, in the context of work eg, first responders, experiencing repeated or extreme exposure to aversive details of the event. If the trauma exposure criterion has been satisfied, diagnosis requires meeting the specified number of symptoms for the disorder, along with duration, distress, and impairment criteria. In acute stress disorder, the disturbance persists for at least 3 days to 1 month; for PTSD, the disturbance persists for more than 1 month. A diagnosis of PTSD requires 1 or more symptoms of intrusion (eg, recurrent, distressing memories or dreams; dissociative reactions; physiologic reactions to internal or external cues related to the event); 1 or more symptoms of avoidance (eg, of distressing memories or external reminders of the event); 2 or more symptoms of negative cognition or mood (eg, inability to remember an important aspect of the event, persistent negative emotional state, diminished interest in significant activities); and 2 or more symptoms of hyperarousal (eg, irritable, reckless, or self-destructive behavior; hypervigilance; sleep disturbance). A separate set of symptom clusters (not presented) pertains to children younger than age 6 years. The major differences in the PTSD criteria for very young children include the requirement for only 1 or more avoidance or negative cognition/mood symptom, the elimination of symptoms requiring reflective cognitive ability, and the expression of intrusion symptoms in play rather than verbally.

#### **Treatment**

Recovery from a disaster occurs across several distinct phases. In the impact phase (immediate aftermath), efforts focus on restoring children's and families' sense of safety and security (eg, provision of basic needs including food, water, and shelter). In the short-term adaptation phase (first 3 months), efforts focus on limiting the youth's ongoing exposure to the trauma and decreasing negative psychological reactions to the trauma. In both of these phases, interventions may be provided in a broad range of venues (eg, emergency shelters, family assistance centers, medical and pediatric health care settings, schools, community agencies) by a broad range of personnel (eg, trained volunteers, PCPs, school and community agency personnel). In the medium- to long-term recovery phase (3 months or longer), efforts focus on facilitating controlled re-exposure to the traumatic event, emotional and cognitive reparative reprocessing of the event in a safe setting, and the development of coping skills. These interventions typically are provided in mental health settings.

Psychological first aid is the primary intervention used during the impact phase of a disaster. Several organizations, including the National Child Traumatic

Stress Network (NCTSN), the National Center for Post-traumatic Stress Disorder (NCPTSD), and the American Red Cross, have developed modular approaches to psychological first aid for use by mental health responders in diverse settings under diverse conditions. Psychological first aid focuses on establishing contact, reducing physiologic hyperarousal, offering and mobilizing support and psychosocial assistance, providing accurate and timely information about disaster reactions and available resources, and conducting ongoing assessments of functional status with triage and referral as indicated.

Beyond psychological first aid, specific clinical approaches in the aftermath of a disaster include family outreach and psychoeducation as well as anxiety reduction. Caregivers often underestimate the suffering of their children; thus, family outreach is an important first step in the recovery process. Once contact is established, psychoeducation is employed to normalize disaster reactions, correct distortions and misperceptions, enhance the child's sense of control, encourage use of family and social supports, promote adaptive coping, and assess risk and protective factors. Specific psychoeducational advice that can be given to parents of children of different ages is presented in Box 370-15. Several organizations, including the American Academy of Child & Adolescent Psychiatry ([www.aacap.org](http://www.aacap.org)), the American Red Cross ([www.redcross.org/services/disaster](http://www.redcross.org/services/disaster)), FEMA ([www.fema.gov](http://www.fema.gov)), the National Association of School Psychologists ([www.nasponline.org/resources](http://www.nasponline.org/resources)), and the NCTSN ([www.nctsn.org/nctsn](http://www.nctsn.org/nctsn)) publish psychoeducational fact sheets and other useful information about coping with disaster events.

The management of anxiety, which dominates the clinical presentation in the aftermath of a disaster, is an essential aspect of the therapeutic response. Recent data have suggested that panic symptoms in the immediate aftermath of trauma exposure are predictive of the development of PTSD. Maintaining routines to the extent possible should help allay anxiety. Specific anxiety reduction techniques include relaxation strategies such as deep breathing and muscle relaxation, and cognitive behavioral strategies such as positive self-talk, problem solving, and scheduling enjoyable activities.

Trauma-focused cognitive behavioral therapy (TF-CBT) has received the most empirical support for the clinical treatment of PTSD. In TF-CBT, the clinician teaches stress management skills in preparation for the exposure-based interventions that are aimed at providing mastery over trauma reminders. The usual components of TF-CBT are presented in Box 370-16.

Evidence derived from one study suggests that intervening early after a traumatic event with brief caregiver-and-child dyadic therapy can significantly reduce trauma-related symptoms. Early intervention focuses on education about normalizing the child's symptoms in the context of trauma; teaching relaxation techniques to address anxiety; and teaching coping strategies to address intrusive thoughts (eg, guided imagery, thought stopping, distraction techniques).

## CONCLUDING COMMENTS

In the face of increasingly frequent psychiatric emergencies, such as those outlined in this chapter, it can

### BOX 370-15 Psychoeducation Guidelines for Caregivers

#### INFANTS AND TODDLERS

- Provide reassurance.
- Return to normal activities as soon as possible.
- Provide soothing activities.
- Avoid unnecessary separation from caregivers.
- Maintain calm among caregivers.
- Avoid television exposure.

#### PRESCHOOL CHILDREN

- Provide reassurance.
- Return to normal activities as soon as possible.
- Provide explanations using simple language.
- Expect and tolerate regressed behavior.
- Expect and tolerate repetitive play about the event.
- Avoid media exposure.
- Censor adult conversations about the trauma.
- Give honest answers (OK to say, "I don't know.").

#### SCHOOL-AGED CHILDREN

- Maintain routines.
- Expect and tolerate repetitive play and retelling of the event.
- Give the child control over choices.
- Provide clear and honest answers.
- Allow the child to discuss the event at her own pace.
- Check with school and other caregivers to assess the child's functioning.
- Limit media exposure.

#### ADOLESCENTS

- Be flexible around routines.
- Discuss family, work, school changes.
- Reassure and normalize strong emotions.
- Try to delay any major changes.
- Encourage involvement in enjoyable activities.
- Provide access for conversations, but do not push.
- Limit media exposure.

prove useful for PCPs to establish collaborative partnerships with mental health clinicians. These partnerships can provide physicians with consultative, educational, and case-management services that are important to ongoing patient care. Such partnerships are crucial to having a responsive pediatric medical home wherein the physical and emotional needs of children and their families are fully addressed.

## TOOLS FOR PRACTICE

### Engaging Patient and Family

- *Coping With a Disaster or Traumatic Event* (Web page), Centers for Disease Control and Prevention ([www.bt.cdc.gov/mentalhealth](http://www.bt.cdc.gov/mentalhealth))
- *Mental Health Care: Who's Who* (fact sheet), American Academy of Pediatrics ([www.healthychildren.org](http://www.healthychildren.org))

### BOX 370-16 Components of Trauma-Focused Cognitive Behavioral Therapy

- Psychoeducation
  - Educating the child and parent about the nature of the traumatic event and expected trauma reactions.
- Parenting skills
  - Use of effective parenting interventions (contingency management).
- Relaxation skills
  - Focused breathing, progressive muscle relaxation, positive imagery.
- Affective modulation skills
  - Identification of feelings, use of positive self-talk and thought interruption, enhancing safety, problem solving, and social skills; recognizing and self-regulating negative affective states.
- Cognitive coping and processing
  - Recognizing relations between thoughts, feelings, and behaviors; changing inaccurate and unhelpful thoughts.
- Trauma narrative
  - Creating a narrative of the child's experience of the trauma; correcting cognitive distortions; placing the experience in the context of the child's whole life.
- In vivo mastery of trauma reminders
  - Graduated exposure to feared trauma-related stimuli.
- Conjoint child–caregiver sessions
  - Child shares trauma narrative with caregiver; other family issues are addressed.
- Enhancing future safety and development
  - Prevention of future trauma; return to normal developmental trajectory.

## Chapter 371 RAPE

Marianne E. Felice, MD; Christine E. Barron, MD

Rape is a legal definition, not a medical diagnosis; every state has statutory definitions of sexual assault and rape. Physicians should be familiar with the statutes in their local jurisdictions. (See Tools for Practice: Community Advocacy and Coordination at the end of this chapter.)

In general, *rape* refers to sexual intercourse with force or the threat of force or without a person's consent. Sexual intercourse may include penile-oral, penile-vaginal, or penile-anal penetration. The threat may be an overt physical threat, a verbal threat, or an implicit threat as a result of age and power differentials between sexual partners. In 2012, The Uniform Crimes Report implemented a new definition of rape: "The penetration,

no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim.” Rape can occur at all ages; however, this chapter focuses on adolescent survivors of rape. Rape entails an assault acted out sexually, rather than a sexual act per se. Not only is rape an unchosen act for the victim, but it also causes unchosen health risks. In this chapter, information is provided on rape, not chronic sexual abuse, such as incest.

## INCIDENCE

Exact statistics on the incidence and prevalence of adolescent rape are not available because many survivors never report the crime. Estimates of unreported rape range from 40% to 90%. Between 40% and 60% of all rape survivors are younger than 18 years, and most are adolescents.

Although national rates of rape have decreased, female adolescents aged 12 to 19 years remain the group at greatest risk. Female adolescents aged 16 to 19 years are 4 times more likely to be sexually assaulted than women in all other age groups. Worldwide, estimates indicate that between one-third and two-thirds of rape victims are 15 years of age and younger. Although most rape victims are women, 5% to 10% are men. Ninety percent of adolescent rape victims are assaulted by someone they know, and more than 50% of these cases occur on a date. Survivors of prior sexual abuse are at particular risk for subsequent assault. Adolescents who engage in high-risk behaviors, such as running away and using drugs and alcohol, are at an increased risk for rape. Approximately one-half of all reported rapes in the United States eventually lead to arrests; approximately two-thirds of those arrested are prosecuted, and approximately one-half of those prosecuted are found guilty. In other words, for every 100 reported rapes, only 16 of the perpetrators are convicted.

## TYPES OF RAPES

Types of rape vary considerably based on the relationship of the victim to the assailant. The various types of rapes raise different issues that are crucial to consider when providing care for the adolescent survivor. Psychosocial sequelae of rape often vary according to the type of rape involved.

### Known Assailant

In most reported pediatric rape cases, the injured child knows the assailant, who may be a parent, a stepparent, an adult relative or friend of the family, a neighbor, an acquaintance, or a classmate. This relationship may cause conflicting family or social loyalties. In these cases, the rape is less likely to be reported. Furthermore, rape survivors who know their assailants are prone to self-doubt and self-blame, and when they do report the rape, their reports may be received with skepticism and disbelief, even by the professionals to whom they turn for help.

### Stranger Rape

An estimated 15% to 55% of reported rapes are committed by individuals who are not known by the person

who is assaulted. Stranger rape is more likely to entail threats or use of violence and fear of immediate danger, and it is associated with a higher incidence of reporting the rape and of subsequent conviction of the assailant. Stranger rape is most likely to occur in areas of poverty and in high-crime districts where walking and playing outside pose risks of danger.

### Date Rape

Estimates of the incidence of date rape vary. However, in a survey of middle and high school students, nearly 20% of the girls and more than 10% of the boys reported a history of unwanted sexual activity on dates. Surveys of college students indicate that approximately 25% of female students and 6% of male students report a history of sexual assault that meets the definition of rape while on a date. Almost none of the college students in these surveys reported the sexual assault to authorities. Particularly in cases of young female adolescents (ages 10 to 15 years) and older men, questions of statutory rape arise, along with questions of consent, refusal skills, and exploitation.

Of the various types of rape, date rape is the least likely to be reported. Of particular concern is the fact that the incidence of date rape seems highly correlated with one or both parties engaging in drinking alcohol or using other drugs before the rape. As would be expected, date rapes are more likely to occur on weekends between 10 pm and 1 am, in automobiles, or at the home of the assailant.

Date rape may not be reported if the rape was facilitated by the administration of pharmaceuticals, including  $\gamma$ -hydroxybutyric acid (GHB), flunitrazepam (Rohypnol), and ketamine hydrochloride (Ketamine), known as *date rape drugs*, given that these medications cause anterograde amnesia.

Trust, self-blame, and vulnerability are important long-term issues for survivors of date rape, as in any other form of rape. The female date rape survivor may not trust her judgment concerning men, and she may blame herself for the rape, erroneously believing that she did not resist clearly or did not resist convincingly enough. She may be ashamed that she ended up in a situation that resulted in rape. These thoughts of guilt may be reinforced by the response and degree of support provided by parents, guardians, and friends. Parents' and friends' understanding and support are significant prognostic factors for recovery. The tendency for survivors to have reservations about reporting date rape is easy to understand. Unfortunately, such secrecy also applies to discussing the incident in general, making catharsis, as well as verbal and emotional support from others, difficult to obtain.

### Gang Rape

Gang rape typically involves a group of young men raping a solitary female. This type of rape may be associated with ritualistic behavior, or sexualized rites of passage. Issues of sexualized rites of passage apply both to stereotypical adolescent gangs and to college fraternities. Survivors of college campus gang rapes are more likely to not report to police.

## Male Rape

In this discussion, *male rape* refers to same-sex rape. Although sporadic reports have surfaced of male rape by women, data are limited. The area of male rape remains understudied and is far less understood than female rape. Specific subgroups of young men are at particular risk for sexual abuse: those in institutionalized settings (such as the criminal justice system), street youth (who may engage in survival sex), young male homosexuals (who may be runaways), and youth who have a parental history of physical or sexual abuse (parents who were abused themselves may become abusers as adults). The occurrence of male rape in institutionalized settings is often attributed to displaced heterosexual behavior or undifferentiated sexual orientation, along with aggressive dominance of a weaker partner. Male rape outside institutions often occurs through coercion by an individual perceived as an authority figure.

Although male rape survivors are more likely than their female counterparts to sustain physical trauma, the treatment of males should parallel that described for women. Issues of loss of control are particularly relevant for the male rape survivor, along with subsequent symptoms of depression, anxiety, sleep disturbances, and suicidal ideation. Conflicted sexual identity is common among male rape survivors, whether they are homosexual or not. Males are often controlled by entrapment, intimidation, physical force, or any combination. The intimidation is accomplished by threats of physical harm, by brandishing a weapon, or both. They frequently perceive the rape as a life-threatening event (a perception that may result in long-term psychological problems). Because of the pervasive reluctance of boys and men to report rape, the preclusion of social support and intervention is a particularly challenging issue.

## MALE PERPETRATORS

Just as female adolescents constitute a large proportion of reported rape assaults, male adolescents make up a large proportion of convicted rape assailants; males under age 18 were arrested for 14.4% of all forcible rapes in 2009 and 17.2% of all sex offenses in 2009.

Perpetrators tend to fall into 1 of 3 clusters: those for whom anger is the primary dynamic; those for whom power or conquest is the central issue; and the sadistic person, for whom anger and control are, in and of themselves, erotic. For the anger-driven rapist, the act tends to be impulsive, with the intent of hurting, humiliating, and degrading the target of the assault. Physical brutality is common. Rape functions as the outlet for anger, essentially by using sex as a weapon. The power-oriented rapist is more likely to engage in premeditated, obsessive, or stalking behavior, in which the rape essentially compensates for social and sexual incompetence or inadequacy. Aggression for the power-oriented rapist is less likely to be violent than a means of dominating his prey. Both anger- and power-driven rapists have serious deficits in social skills and the inability to interpret and respond to social cues from others. For the sadistic rapist, eroticism and violence are enmeshed; victims are typically subjected to premeditated, deliberate

acts of cruelty and dehumanization. The sadistic perpetrator finds gratification in inflicting pain and powerlessness.

Although some rapists are sexually dysfunctional at the time of the rape, most rapists are sexually active with available, consensual partners outside the rape. Perpetrators usually seem ordinary by most standards; most do not have symptoms of major psychiatric illnesses such as psychoses, nor does a preponderance exist of intellectual disability. However, other conditions such as antisocial, schizoid, paranoid, and narcissistic personality disorders are noted more commonly among convicted rapists than in the general population.

The use of alcohol and drugs has been associated with the occurrence of rape. Ironically, alcohol intoxication sometimes seems to have the effect of both diminishing a perpetrator's sense of responsibility and increasing a survivor's perceived culpability. Specifically, the perpetrator's act of rape is *excused* because he was drinking and not responsible for his actions, whereas victim intoxication is consistently coupled with the process of *unfounding*, or disproving, rape charges.

## RESPONSE TO RAPE

### Immediate Response to Rape by the Survivor

Immediate responses to rape vary considerably, ranging from distraught histrionics to near-mute withdrawal. Most survivors have intense levels of fear and anxiety. Varying levels of cognitive disorganization, shock, and disbelief also characterize this postrape acute phase. As occurs in any crisis, many adolescents regress to previous stages of development. An adolescent rape survivor who was previously self-assured and appropriately independent may become clinging and dependent on the parent or health professional.

### Immediate Response by the Family

Unlike other crime victims, the survivor of rape rarely contacts the police immediately. Typically, the first contact is with an intermediary such as a friend or family member. This individual's response is crucial in the ensuing medical and legal processes; but most family and friends need guidance to know how best to be supportive. The disclosure of rape is usually traumatic for the family as well as the survivor. Parents may blame themselves inappropriately for the rape. In other instances, parental activities (eg, neglect) may have contributed to the rape. In either scenario, the issues are highly sensitive and need to be addressed with skill and compassion.

Familial responses to a child's rape range from denial and disbelief to shame and outrage. No guarantee exists that a family is prepared to respond appropriately to a raped child's needs at this time. In some cases, a mother's financial dependence on a perpetrator may confound reactions. During the initial evaluation session, health care professionals must therefore spend some time with the family members and friends of the survivor to determine their own psychological response and their ability to be supportive.

## LEGAL ISSUES

All states have laws that require physicians to report cases involving violent assault, including rape. To report statutory rape, the physician should be familiar with the state's laws regarding report of sexual abuse and the legal age of consent. Statutory rape is defined as sexual activity of an adult with an adolescent under the age of legal consent. Reporting concerns include the possibility that reporting statutory rape can cause barriers for adolescents to obtain appropriate medical care. Physicians have expressed the desire to use their clinical judgment in reporting cases of sexual activity that fall within the definition of statutory rape. Some states require parental notification of a minor's sexual assault, and in those states, this statute overrides issues of confidentiality.

Most states permit a minor to receive treatment for sexual assault without parental consent. All physicians must be familiar with local statutes. Physicians should seek additional guidance from their legal counsel or from their state attorney general's office.

Consent for treatment of rape is different from consent for collection of evidence. An adolescent patient above the legal age of consent has the ability to consent to a medical evaluation and treatment and refuse collection of forensic evidence, or the adolescent may consent to both. Many survivors are reluctant to give permission because they fear social isolation and possible retribution by the perpetrator. Those who decide not to report the rape to law enforcement should be informed that if they want to pursue possible prosecution in the future, then the evidence must be collected at this time. Therefore, the physician must ask the adolescent patient for permission to complete a full evidentiary examination and to release the evidence to the police. Cases of child sexual abuse in which state law requires reporting to a child welfare agency, law enforcement, or both are an exception; such cases do not require consent from patient or family to report.

From a medical-legal perspective, physicians must realize that their responsibility is limited to the documentation of evidence. Determining whether a rape really occurred is not the physician's role; this determination is a court decision. The physician will be of most help by providing appropriate nonjudgmental support for the patient, being thorough in the evaluation, and keeping accurate medical records.

## MEDICAL EVALUATION

Rape is a serious medical and psychological emergency for both the survivor and the family. The purpose of the initial evaluation is 4-fold: treatment of injury and infection, prevention of pregnancy, collection of evidence, and psychological assessment with referral for follow-up counseling.

### General Concepts

Many metropolitan areas have treatment centers with trained interdisciplinary teams available for adolescent and child survivors of rape; these treatment centers are ideal sites for an initial evaluation and are usually staffed with an interdisciplinary care team, most frequently consisting of a physician, nurse, and

social worker. An interdisciplinary approach is beneficial for several reasons, including the ability to provide support to the child and family simultaneously and to serve as a resource for future services. For various reasons, most pediatric rape survivors do not use such specialized facilities, and they may receive medical evaluations at emergency departments or private medical offices. To minimize the physical and psychological trauma of the evaluation, eliminate the need for repeat evaluations, and maximize the probability of collecting forensic evidence, the most skilled professional available should perform the initial evaluation. The gender of the examiner is less important than the individual's comfort with adolescents and children, skill at conducting the examination, and level of compassion.

The rape evaluation can be long and tedious, but it should never be rushed. Although the youngster is coping with personal outrage and physical and psychological pain, the patient is expected to tolerate and cooperate with uncomfortable procedures that may feel similar to the acts of intrusion and aggression experienced previously. The approach to the evaluation should be calm, gentle, and private. Rape protocols, if available, are helpful and will serve to minimize the chance for error or omission in the evidence-collection process. Most jurisdictions have printed standardized forms for the evidence-procurement process; these forms are available in each state's *forensic evidence kit*. Before the examination, the physician should become familiar with these forms.

The physician should avoid making inappropriate assumptions based on the patient's psychological state. Many survivors are in a state of shock or denial immediately after the event. How a patient responds in the emergency department varies and depends on numerous factors, including developmental maturity. Seeming physically mature but functioning cognitively at the level of a preadolescent is not uncommon. Therefore the patient's psychological state should not alter the physician's approach to care. Furthermore, the physician should not attempt to minimize the patient's sense of personal guilt, shame, and anxiety by offering reassurance immediately. Taking a few minutes to empathize with and acknowledge the patient's feelings before proceeding with the evaluation helps both the patient and the physician. Particularly in cases in which acute trauma may compromise coping skills, the establishment of the patient's safety is crucial. The physician should never leave the patient alone, if at all possible.

Taking whatever time is necessary at the beginning of the examination to explain the process and allow for questions is always prudent, particularly for rape survivors who have not had a previous sexual relationship or a prior gynecologic examination. Some may also be fearful of anticipated pain and discomfort. Whenever possible, the physician should allow the patient some control over the proceedings; the patient should set the pace of the examination. The physician should be careful to inform the patient in advance of what tasks must be accomplished. Whenever applicable, making reference to prior experience with other rape survivors of a similar age may help establish that

the patient is not the only child or adolescent to whom this ordeal has happened; it also establishes that the physician is not shocked at such circumstances and has some practical knowledge with which to anticipate concerns. The patient should be the one who signals when to begin the procedure. If he or she becomes visibly agitated with the proceedings, then the physician should stop and allow the patient to regain composure before continuing with the examination. At no point should a physician continue the examination against the child or adolescent's will.

After obtaining consent from the patient, the physician should obtain a detailed and relevant history, followed by a thorough general physical examination and a gentle but complete pelvic examination. A female nurse or assistant must be present during this process; for some young adolescents, having a parent present during the examination is helpful if the parent is reassuring, rather than openly distraught, during the procedure. Some aspects of the evaluation will change depending on the temporal proximity of the evaluation to the alleged event. The following guidelines are recommended for evaluations conducted within 72 hours of the assault. Modifications are necessary if the evaluation is conducted after this time. In some centers the interdisciplinary team obtains the history simultaneously and together so that it does not have to be repeated unnecessarily.

### History

History taking necessarily entails asking some very personal and potentially awkward questions. The patient should be assured of privacy and offered respectful compassion. The history should include the time, date, and location of both the event and the examination. Recalling the event may be emotionally traumatic for the patient; thus, beginning with a relevant, but relatively neutral, medical history is sometimes useful. Such information as general medical history, physical and behavioral symptoms, and a thorough menstrual history—including the age of menarche; the date of the last menstrual period; the frequency of menses; sexual activity if relevant; previous pregnancies, miscarriages, and abortions; and the use of contraceptives and feminine hygiene products—is important. Additional history should include parental response to disclosure, fear of parental reaction and risk for running away, and fully exploring past and current suicidal ideation.

Next, the event itself should be the focus. Questions should be asked calmly and with sensitivity and patience. The patient's own words should be recorded whenever possible. The medical chart is a legal document and will be subjected to the same scrutiny as any other form of evidence. Only the historical facts, without embellishment or interpretation, should be recorded.

The patient should be asked about the use of intoxicating substances before or during the event, as well as whether any loss of consciousness that may have occurred. The physician needs to ask whether weapons or restraints were used during the assault. The patient should be asked to describe in detail the location of the event, the appearance of the perpetrator,

the type of sexual contact and the positions used, the use of force (by both parties), the removal of clothing and the manner in which it was removed, and what measures, if any, the patient took to cleanse or relieve herself or himself (eg, bathing, douching, changing clothes, urinating, defecating). Whether the assailant used a condom or any other means of contraception should be determined. Finally, the physician should ask about the presence of clinical symptoms in the musculoskeletal, gastrointestinal, and genitourinary system.

### Physical Examination

A detailed history and physical examination, as well as specimens for forensic and laboratory evaluation, should be obtained for all rape survivors who consent to complete an examination. Particular focus should be placed on the evaluation of the oral cavity, the genitals, and the anus.

Although a complete physical examination from head to toe is warranted, 40% to 60% of sexual assault survivors will have no visible physical injuries. Inspection of the entire body may provide the corroborative evidence necessary to convict the perpetrator, and follow-up examinations may reveal emerging bruising or injuries in areas initially noted to have tenderness or swelling but no visible bruising on the initial examination.

The patient's physical appearance and emotional state and the condition of the patient's clothing should be noted. If the patient is still wearing the same clothing as at the time of the event, then its condition should be noted and each piece saved in a separate, labeled bag. Applying a fluorescent lamp to the clothing and skin may illuminate the presence of dried semen. Semen fluoresces best at wavelengths of 420 and 450 nm, when viewed through orange goggles. A Wood lamp emits light at only 360-nm wavelength. Therefore specialized alternate light sources that emit wavelengths at 420 and 450 nm, such as a Bluemaxx, should be used. Although this type of lamp will improve the detection of dried semen, many other substances will fluoresce as well; thus, confirmation of semen cannot be made with this method. These specimens should be marked for later analysis for the presence of seminal vesicle-specific antigen. Next, a topical survey of the body, documenting any evidence of recent trauma or bruising, should be done. Photographs may be useful during subsequent litigation. Use of a diagram to indicate locations of visible injuries can be helpful. The physician should use the fluorescent lamp to identify any fluorescent areas on the skin and obtain swabs of these areas.

Particular attention should be given to the examination of the head and neck. Compression injuries of the neck are fairly common if force is used. This type of injury may lead to obstruction of venous return from the head, causing the development of neck bruising or petechial hemorrhages in the eyelids and conjunctiva. The inner surface of the lips may have tiny abrasions resulting from forced pressure applied to the mouth by the perpetrator to prevent screaming. Common injuries to the mouth include torn frenula and palate petechiae.

The breasts may show bite marks or bruises. The physician should swab all bite marks to collect genetic markers (ABO group) and photo-document these injuries because the bite impression may be matched to a potential perpetrator. Tanner staging to determine the level of sexual maturation (breasts and pubic hair in female patients, genitalia and pubic hair in male patients) should also be performed.

### Genital Examination

#### Female Patient

After the initial physical examination, the patient can be draped and placed in the lithotomy position. If the patient seems too anxious and a speculum examination is not required to investigate for a source of undiagnosed internal bleeding, then the supine frog-leg position may be a suitable alternative. A speculum examination is not necessary for younger adolescents or children unless active vaginal bleeding is present, which is a rare occurrence. In these rare instances of active vaginal bleeding, performing the pelvic examination with the patient under sedation or under general anesthesia may be necessary.

The pelvic examination should begin with inspection of the thighs and perineum for evidence of trauma, bruising, semen, or blood. Appropriate forensic evidence should be taken at this time (Box 371-1). General inspection of the external genitalia should be performed, with documentation of any erythema, edema, ecchymosis, or abrasions noted.

In some cultures, an intact hymen is important as an indicator of virginity, and the patient and parents will be concerned with its structural integrity. An intact hymen does not rule out the diagnosis of rape. Acute injuries to the hymen such as bruising, petechiae, or acute transactions should be documented by describing any active bleeding and the location, as though a face of a clock were superimposed over the hymen (eg, acute swelling and transaction of hymen with active bleeding at 8-o'clock position). The entire rim of the hymen must be visualized; proper labial traction

along with a saline-moistened cotton swab rolled around the edges of the hymen is necessary. The use of a light source or the application of aqueous toluidine blue (1%) to the posterior fourchette may help locate and identify acute tears. Many experts use colposcopy, which provides a light source, magnification, and photo-documentation of the examination. Colposcopy or photo-documentation with a camera is essential in providing documentation of the examination, and images can later be evaluated by expert review.

Older female adolescents should be able to undergo a speculum examination of the internal genitals, which will allow a clear view of the vaginal walls, fornices, and cervix. Appropriate specimens for culture and forensics should be obtained (see Box 371-1).

#### Male Patient

The testes, epididymis, vas deferens, penile shaft, foreskin, and glans penis should be examined thoroughly for the presence of infection or trauma.

### Anal Examination

A history of sodomy in either males or females indicates the need to conduct a thorough anal inspection. The physician should document any erythema, ecchymosis, abrasions, or rectal bleeding noted. Aqueous toluidine blue (1%) may be applied to help visualize acute microtrauma to the perianal area.

### Summarizing the Examination

When the physical examination is complete, the patient should be given ample time to dress and regain composure before discussing any findings. Most patients will benefit from knowing that their genital anatomy is normal. Several studies have demonstrated that more than 90% of anogenital examinations performed after rape are normal. It is also important to discuss physical findings, treatment options, and plans for follow-up.

### Forensic and Laboratory Information

The recovery of laboratory and forensic data is probably the most controversial aspect of the evaluation, especially when recovery of semen and sperm is involved; nonetheless, the finding of male ejaculate is neither predictive nor essential for criminal conviction. In one study, physical evidence of rape was found in only 23% of all the cases that resulted in felony convictions. Forensic evidence identified in younger children is more often obtained from the clothing, bed linens, or both. There are on-going developments in forensics science for the laboratory analysis of semen.

### Sexually Transmitted Infection

Most patients are concerned about the risk for acquiring a sexually transmitted infection (STI) as a result of the rape. This risk is related directly to the health status of the assailant and the victim, the site of the assault, and the infectivity of the disease in question. Overall, the risk for contracting an STI from a single encounter is small. Repeat assaults or assaults by more than a single assailant increase the risk for infection. Many adolescents, however, also engage in high-risk behaviors that put them at increased risk for

#### BOX 371-1 Recommended Procedures for Collecting Forensic Data

- Forensic evidence kit: complete forms for authorization and release of evidence, history, and physical examination. Individual envelopes will be completed if indicated by the history provided.
- Additional tests:
  - Pregnancy test
  - Syphilis screening
  - HIV test
  - Cultures for gonorrhea (oral, urethral, vaginal, and anal)
  - Cultures for *Chlamydia* (urethral, vaginal, and anal)
  - Wet mount for detection of *Trichomonas* and spermatozoa

While culture is the gold standard, there are some institutions that use NAAT testing for Gonorrhea, Chlamydia, and Trichomonas

having a preexisting STI. Additionally, as many as 50% of sexual assault survivors do not return for follow-up appointments. The Centers for Disease Control and Prevention recommend using prophylactic antibiotics for treating potential sexually acquired infections (see Chapter 330, Sexually Transmitted Infections). A prophylactic hepatitis B vaccination against possible exposure is recommended.

Regardless of the antibiotics given, the physician must emphasize to the patient that the incubation period for STIs varies and that an infection may not be detected or may be missed or treated inadequately at the time of the evaluation examination. Therefore, although baseline studies should be obtained at the initial evaluation, medical follow-up is absolutely crucial. After 2 weeks the patient should be re-examined for the presence of an STI. Serial testing for syphilis, human papillomavirus, and HIV infection should be performed after the assault in most cases.

### Pregnancy

The occurrence of pregnancy after rape is strongly influenced by whether a female patient is in the fertile interval of her menstrual cycle, as well as by the possible sexual dysfunction of the assailant (eg, failure to maintain an erection or to ejaculate). Many adolescents, however, have irregular menstrual cycles; therefore, the occurrence of ovulation for any particular cycle may be in question. If the assault occurred within 5 days of the evaluation, then emergency contraception (see the discussion of postcoital *morning after* contraception in Chapter 123, Contraception and Abortion) should be offered to the patient after a negative pregnancy test has ruled out the presence of an already existing pregnancy. Two types of emergency contraceptive medications are available. The first type contains only progestin. Plan B is a progestin-only emergency contraceptive that reduces the risk for pregnancy by 89%. Because Plan B contains only progestin, it has fewer side effects of nausea or vomiting. The second type contains both progestin and estrogen. Most brands of the daily oral contraception pill contain both progestin and estrogen and reduce the risk for pregnancy by 75%. When medication containing both progestin and estrogen is used, antiemetics should be offered because of the frequent side effects of nausea and vomiting. The occurrence of pregnancy after unprotected exposure should be strongly suspected when menses does not occur within 4 weeks of the rape, at which point the patient should return for a repeat evaluation.

### PSYCHOLOGICAL ASSESSMENT

The psychosocial and emotional implications of rape in children and adolescents are complex. This circumstance is tempered further by the young person's stage of development and the family's response to the rape. For example, young adolescents who are just beginning to grapple with their own sexuality may believe that they deserved to be raped because of having begun to experience sexual urges. A female child who sees her mother respond with tearful distress to the news that her child was raped may feel guilt not

just because of the rape but also because of the emotional trauma inflicted on the mother.

How the youngster copes with the rape is also related to how society responds to survivors of rape. Unlike most crimes, the crime of rape is often blamed on the victim rather than on the perpetrator, particularly in adolescents. Following no other crime are the victim's prior reputation, appearance, and behavior subject to such scrutiny as in rape. Running away, sexual activity, and even hitchhiking are used as justification for the rape, placing further blame on an already troubled young person. Physicians must avoid compounding such punitive dynamics.

### Follow-up Care

After the initial evaluation is complete, arrangements should be made for follow-up care, not only for the medical issues discussed previously, but also to assess the victim's ability to cope with the rape and to accept counseling concerning the rape. All rape survivors and their families should be seen as soon as possible after the rape by a mental health professional who is trained to work with adolescents and who is knowledgeable about the emotional sequelae to rape.

### Short- and Long-Term Psychological Sequelae

Multiple factors will determine how a child or adolescent responds to the rape; these factors include level of social support, coping styles and strengths, and developmental variables and cognitive functions. How any given individual will respond to rape cannot be predicted. However, children and adolescents who have been raped experience a variety of both short-term and long-term consequences. In addition, sexually traumatized children have been noted to have higher levels of precocious sexualization than non-traumatized children. Confusion may exist about what is normal adult sexual behavior, sometimes leading to inappropriate sexual acting-out behaviors. Some children experience developmental arrests at the time of the trauma; such arrests are not necessarily readily apparent. Although child and adolescent studies are still too scarce to be considered definitive, apparently the earlier and more traumatic the rape is, the greater the chance is of developmental and functional impairment.

Behavioral concerns frequently associated with adolescent rape sequelae include school phobias, generalized fearfulness and withdrawal, and, especially in adolescents, the onset of truancy. Suicidal ideations are not uncommon, with increased lifetime risks for major depression and suicide attempts being associated with women in the aftermath of rape. For male rape survivors the existing research is less clear; however, male sexual trauma in childhood may be associated with sexually abusive behavior toward other boys during adolescence. Obviously, although not all children and adolescents who have been raped will have psychiatric sequelae, all of those who have been raped should be assessed and monitored for serious sequelae. Particularly in cases in which sexual acting out follows a rape, careful clinical attention to issues such as posttraumatic stress disorder and depression

is required. Self medication with various substances is an ongoing clinical hazard after rape and deserves consideration as a *red flag* for physicians working with at-risk patients.

## SUMMARY

Rape is an act of violence that involves a disparity of power between the perpetrator and the victim. Because of its sexual context, rape is easily misinterpreted as erotic or sexual behavior, which it is not.

Adolescents who have been raped should have sensitive and thorough evaluations and follow-up assessments. From the time of initial disclosure through eventual legal outcome, many developmental, familial, and social variables can shape the experience for young survivors and their families. Long-term adjustment following rape varies considerably, with both developmental and familial factors having considerable effect.

## TOOLS FOR PRACTICE

### Community Advocacy and Coordination

## Chapter 372

# SEVERE ACUTE ASTHMA (STATUS ASTHMATICUS)

Alan R. Schroeder, MD; David N. Cornfield, MD

Asthma is a major cause of morbidity and mortality in children. Asthma exacerbations impose a significant strain on health care systems and can compromise the quality of life of patients and their families. Asthma death rates in US children increased progressively between 1980 and 1999, with the highest mortality rates in blacks. In recent years, asthma death rates have been relatively stable, and overall hospital admissions actually decreased by 50% from 1992 to 2006. Severe acute asthma (*status asthmaticus*) generally refers to an acute exacerbation that does not respond to initial doses of nebulized bronchodilating agents, thereby placing the asthmatic patient at risk for respiratory failure.

Risk factors for near-fatal and fatal asthma differ across studies and between pediatric and adult populations. The risk for fatal or near-fatal asthma is greater in patients with more long-standing disease and in patients with more severe disease. Signs of increased asthma severity include multiple hospitalizations, prior intubations, and previous attacks with severe, unexpected, and rapid deterioration. Many studies have demonstrated associations between  $\beta$ -agonist use and death or near death, likely representing an epidemiologic phenomenon whereby  $\beta$ -agonist use is a marker for more severe asthma. A putative link also exists between the use of long-acting  $\beta$ -agonists and significant adverse events. The association between significant adverse events and  $\beta$ -agonist exposure underscores the importance of familiarity with a patient's medical regimen when treating an asthma exacerbation. Abrupt cessation of inhaled corticosteroids may further increase risk for death.

Overall, most asthma deaths (80%–85%) occur in patients with severe and poorly controlled asthma with progressive deterioration characterized by histologic evidence of extensive mucous plugging and eosinophilic inflammation. These patients tend to respond slowly to treatment. More optimal chronic anti-inflammatory therapy may assist in preventing the death of these patients. A smaller proportion of deaths occur in patients who have acute deterioration (eg, sudden asphyxic asthma), in whom mucous plugging is substantially reduced and the inflammatory cells are neutrophils. These attacks are less preventable given their acute onset; however, if appropriately treated, they usually demonstrate faster response to treatment.

## CLINICAL MANIFESTATIONS

Asthma exacerbations are most frequently triggered by viral infections in children. Other common triggers include aeroallergens (animal dander, dust mites, molds, and pollens), cockroaches, tobacco smoke, pollutants, cold or dry air, exercise, and laughter.

The hallmark of asthma is cough and wheezing, although wheezing may not be evident if air entry is limited. Patients in status asthmaticus may complain of shortness of breath or chest tightness and demonstrate signs of increased work of breathing, including tachypnea, accessory muscle use, nasal flaring, head bobbing, and grunting. Patients may have difficulty speaking or completing short sentences in one breath. Patients are often anxious and, in severe cases, may have altered mental status or lethargy. Signs of impending respiratory failure include cyanosis, decreased breath sounds, altered level of consciousness, diaphoresis, and inability to speak more than a few words or phrases with a single breath.

Physical examination should include a complete set of vital signs, including pulse oximetry. Patients in status asthmaticus often have tachycardia, tachypnea, hypoxemia, and pulsus paradoxus, defined as an accentuation of the physiologic drop in systolic blood pressure by greater than 10 mm Hg during inspiration. Close attention should be paid to the level of consciousness, hydration status, and peripheral perfusion. The eyes, ears, nose, and throat should be examined to assess for a possible source of infection that may have triggered the asthma. The nares should be inspected for polyps and signs of allergic rhinitis. A heart examination is necessary to rule out a cardiac cause of wheezing. During the abdominal examination, hepatomegaly may be noted if the lungs are hyperinflated.

The chest should be directly inspected to assess the work of breathing, to assess for the presence of chest wall deformities, and to observe whether chest movement is bilaterally symmetrical. Auscultation should be performed to evaluate air entry (depth and symmetry), determine inspiration-to-expiration ratio, and detect wheezing or rales. Spirometry is helpful in older children and should be performed serially to follow the disease trajectory, but is of little value in the context of an acute exacerbation. Comparison of peak expiratory flow rates to baseline values or to normal values based on age and height can be helpful in assessing the severity of an acute exacerbation.

Chest radiographs are often ordered but rarely add meaningfully to the diagnosis and management of severe asthma exacerbations. Findings may include bilateral hyperinflation, an area of opacification, and, rarely, pneumothorax or pneumomediastinum. The history and physical examination should guide the decision to obtain a radiograph. Indications include asymmetry or focal abnormality on auscultation, endotracheal intubation, and a suspicion of foreign body aspiration, in which case unilateral hyperinflation may be present. Pulse oximetry and arterial, venous, or capillary blood gas analysis can provide additional assessment of the adequacy of ventilation and oxygenation, although needle sticks may increase anxiety and distress in a borderline patient. Hypoxemia and respiratory alkalosis are present initially, but the pressure of carbon dioxide in the blood will slowly start to increase as airway obstruction increases. Historically, a finding of carbon dioxide retention has been considered as an indication for endotracheal intubation and mechanical ventilation. However, more recent reviews advocate basing escalation of therapy and intubation decisions on clinical parameters, such as altered mental status or hemodynamic instability, rather than blood gas results alone.

Patients with severe acute asthma may have some degree of metabolic acidosis caused by either compensatory renal bicarbonate loss (as compensation for respiratory alkalosis if the exacerbation has been long-standing) or lactate accumulation.

The source of lactic acidosis is unclear, but it may be the result of a combination of high-dose parenteral  $\beta$ -agonist use, anaerobic metabolism from overused respiratory muscles, or tissue hypoxia. The presence of lactic acidosis is an ominous sign, but is rare in children with status asthmaticus, and there is generally no reason to obtain lactate levels in asthmatic patients.

## PATHOPHYSIOLOGIC CONSIDERATIONS

Asthma is an inflammatory condition characterized by widespread, variable obstruction of the lower airways. The airflow limitation results from inflammation of the lower airways, mucosal edema, epithelial sloughing, mucous plugs, and bronchospasm. The inflammation is a complex response that includes eosinophils, mast cells, T lymphocytes, macrophages, neutrophils, and epithelial cells. The primary event is generally activation of mast cells in response to local irritation, which leads to mast cell degranulation and promotes activation of T lymphocytes (Figure 372-1). Multiple proinflammatory mediators are released, including histamine, leukotrienes, platelet-activating factor, and several helper T-cell type 2 cytokines. These cytokines augment immunoglobulin E production by B lymphocytes, thereby increasing leukotriene release from mast cells. Ultimately, this inflammatory environment is rich in leukotrienes, prostaglandins, nitric oxide, and platelet-activating factor, causing overproduction of mucus and epithelial cell destruction. The loss of epithelial cells exposes nerve endings, rendering the airway even more hyperirritable in response to environmental triggers. Epithelial damage is correlated with the severity of airway reactivity.

**Figure 372-1** Cellular mechanisms involved in airway inflammation. (From National Asthma Education and Prevention Program. Guidelines for the Diagnosis and Management of Asthma, Expert Panel Report 2. Bethesda, MD: National Heart, Lung, and Blood Institute, National Institutes of Health, US Department of Health and Human Services; 1997. NIH Publication 97-4051.)

Airway caliber and mucus secretion are regulated by the autonomic nervous system. Bronchial nerve ganglia receive direct vagal innervation, but they are also modulated by circulating catecholamines. Vagal parasympathetic stimulation leads to the release of postganglionic acetylcholine, causing bronchoconstriction, and mucus secretion.  $\beta$  receptors are found on airway smooth muscle, epithelium, and mucous glands, as well as on various inflammatory cells. Stimulation of  $\beta$  receptors causes cyclic adenosine monophosphate activation of protein kinase A, which, in smooth muscle, leads to muscle relaxation and bronchodilation. Polymorphisms in the  $\beta_2$ -adrenergic receptor have been described in children and may explain some ethnic differences in asthma severity and response to bronchodilators.

Airway obstruction compromises inspiratory and expiratory gas flow, leading to ventilation-perfusion mismatch. Distal lung segments become hyperinflated as alveoli empty incompletely. In the respiratory cycle, inspiration begins before exhalation is complete. This process of dynamic hyperinflation creates large end-expiratory lung volumes, which may be evident on clinical or chest radiographic examination. Hyperinflation worsens ventilation as large residual volumes create difficulty in generating effective tidal volumes. As obstruction worsens, hyperinflation can lead to ventilation-perfusion mismatch and hypoxemia. If airway obstruction is not relieved, then muscle fatigue can further compromise ventilation, resulting in hypercarbia and, ultimately, respiratory failure.

The severe obstruction that characterizes status asthmaticus can diminish venous return to the right atrium, thereby decreasing cardiac output. Pulmonary

vascular resistance can be increased by hypoxia, acidosis, and hyperinflation, further increasing the workload of the right ventricle. Spontaneously breathing patients in status asthmaticus generate large negative intrapleural pressures, with inspiratory pressures as low as  $-35$  cm  $H_2O$ . Negative pleural pressure increases left-ventricular oxygen demand and work by increasing left-ventricular transmural pressure. Furthermore, the generous negative intrapleural pressure creates a gradient for fluid movement from capillaries to alveoli, leading to a decrease in cardiac output and a potential for pulmonary edema. Increasing negative pleural pressure can also increase left ventricular afterload, which can have an untoward effect on cardiac output. Pulsus paradoxus occurs when systemic cardiac output drops markedly during inspiration, resulting primarily from increased capacitance of the pulmonary vasculature and resulting in decreased left-ventricular preload.

## MANAGEMENT

### Supportive Care

Any child in status asthmaticus should be hospitalized in a monitored bed. Indications for pediatric intensive care unit (PICU) admission vary across hospitals and may depend on hospital policies and staffing issues. Any child requiring positive-pressure ventilation (PPV), sedation, or continuous intravenous bronchodilator infusions should be monitored in a PICU.

Although significant hypoxemia is rare outside of severe asthma, administration of supplemental oxygen can address hypoxemia and may ease work of breathing. Oxygen can be delivered by nasal cannula,

but, in cases of significant hypoxemia, oxygen can be delivered more efficiently by a non-rebreather or partial non-rebreather face mask. According to National Institutes of Health guidelines, the target oxygen saturation should be more than 90% in most patients.

Most asthma exacerbations are caused by viral infections or noninfectious triggers. Antibiotics should, therefore, not be provided for acute asthma exacerbations except as needed for cases in which a strong suspicion of bacterial pneumonia exists (eg, fever and purulent sputum, chest radiograph demonstrating focal infiltrate). However, it warrants reiteration that many chest radiographs in asthmatic patients demonstrate opacifications because of nonbacterial causes, usually atelectasis, and thus should be avoided in most cases.

Patients are often dehydrated as a result of poor oral intake and increased insensible losses from the respiratory tract. The effects of dehydration on preload, coupled with the cardiopulmonary interactions present in severe asthma and the effect of multiple medications on systemic vascular resistance, highlight the importance of paying very close attention to fluid status and hemodynamics. Rehydration is necessary to maintain euvolemia and cardiac output, but overhydration can lead to pulmonary edema. Urine output and electrolytes should be monitored closely, given that the syndrome of inappropriate antidiuretic hormone may occur in severe asthma.

Patients with respiratory failure or impending failure should be intubated and mechanically ventilated. However, patients with severe asthma should receive prompt and aggressive therapy as soon as possible to avoid endotracheal intubation because manipulation of the airway may exacerbate bronchospasm. Furthermore, PPV, even noninvasive ventilation, increases the risk for pneumothorax and may result in untoward hemodynamic sequelae. Noninvasive PPV prevents the risks inherent in intubation and may be considered as an alternative to intubation and mechanical ventilation. Bilevel positive airway pressure has been used successfully for children in the emergency department with status asthmaticus and, in some cases, may obviate the need for admission to a PICU.

In the event of a clinical decision that respiratory failure is imminent and intubation is necessary, great care must be exercised in the course of induction and intubation. Induction medications that minimize the effects on the patient's cardiovascular status should be chosen. Intravenous access should be established before intubation because administration of analgesic and sedative agents can cause vasodilation, leading to profound hypotension. If a patient is intubated and mechanically ventilated, then sedation should be used.

Neuromuscular blockade may be necessary to minimize peak inspiratory pressures on the ventilator, although neuromuscular blockade may potentiate subsequent muscle weakness. In nonintubated patients, use of sedative-hypnotic agents should be undertaken with caution because such agents can further compromise the respiratory effort. If sedation is used, then objective criteria to assess respiratory status, such as blood gases, should be monitored even more closely than usual. Because of its

bronchodilatory effects, ketamine is the sedative agent of choice, and it has been used successfully in nonintubated and intubated children. However, prolonged ketamine infusions have not been adequately studied.

### Bronchodilators

$\beta_2$ -agonists are the mainstay of bronchodilator pharmacotherapy for severe asthma, and they are most often provided in the inhaled form. These drugs stimulate  $\beta_2$  receptors in airway smooth muscle, leading to smooth muscle relaxation and subsequent bronchodilation. Inhaled albuterol can be given by a metered-dose inhaler with a spacer chamber or by nebulization. Studies comparing the efficacy of the 2 methods of delivery for acute asthma show no significant difference, although patients receiving albuterol by metered-dose inhaler or spacer seem to have a shorter length of stay in the emergency department than patients using nebulization. For severe exacerbations, however, nebulization is generally the preferred route, and continuous nebulization seems to be better than intermittent doses, even when the same cumulative dose is used. The standard dose of continuous albuterol is 5 to 20 mg/hour, although doses as high as 40 to 150 mg/hour have been reported.

The standard formulation of albuterol is a 50/50 mixture of the (R)- and (S)-enantiomer forms of the drug. (R)-albuterol (levalbuterol) is the active form of the drug that leads to bronchodilation, whereas (S)-albuterol has a longer half-life and may contribute to side effects. In 1999, the US Food and Drug Administration approved the use of levalbuterol for asthma. Studies comparing levalbuterol with the racemic form have demonstrated similar clinical efficacy with the 2 preparations, although the cost of levalbuterol is 10-fold greater than that of generic albuterol. For hospitalized patients, continuous nebulized levalbuterol offers no benefit over continuous nebulized racemic albuterol. Thus, there is no reason to use levalbuterol, given its cost, over albuterol. Use of long-acting  $\beta$ -agonists in the treatment of acute asthma is not indicated. Common side effects of inhaled  $\beta$ -agonists include tachycardia, tremulousness, headache, hypokalemia, and nausea and vomiting.

Other  $\beta$ -agonists include epinephrine and terbutaline, which can be given by aerosolized, subcutaneous, or intravenous routes. Epinephrine, although sometimes used subcutaneously, is rarely used by the intravenous route because of its lack of  $\beta_2$  selectivity and the resulting dangerous side-effect profile. Terbutaline is often provided subcutaneously during a severe exacerbation when intravenous access is not readily available. The usual dose is 0.01 mg/kg given subcutaneously every 20 minutes in 3 doses, as necessary. In the PICU, terbutaline can be administered as bolus of 2 to 10 mcg/kg followed by a continuous infusion, with a dose range of 0.4 to 10 mcg/kg per minute. It is generally well tolerated, although it may cause a decrease in diastolic blood pressure. Given in a protocol-based fashion as an adjunct to aerosolized bronchodilators, terbutaline has been shown to reduce length of stay in both the PICU and the hospital. Recent randomized trials, however, failed to show any significant benefit

of terbutaline over placebo in patients already on continuous albuterol, or of terbutaline over aminophylline, which is substantially cheaper.

Anticholinergics are often used as adjuncts to  $\beta$ -agonists in managing status asthmaticus. These agents produce bronchodilation by blocking the effects of acetylcholine-induced bronchoconstriction, and they may have some effect on thinning or reducing secretions. The prototypical anticholinergic drug is ipratropium bromide, which is similar to atropine but has the advantage of not inhibiting ciliary beat frequency and mucociliary clearance. When given as an adjunct to albuterol and corticosteroids, ipratropium has been demonstrated to reduce hospitalization rates of asthmatic children and adults seen in the emergency department for asthma exacerbations. Ipratropium produces minimal systemic side effects, although inadvertent spread of the aerosolized drug to the eyes may cause unilateral or bilateral mydriasis, which can be alarming in a critically ill patient. There is no evidence to support ongoing use of ipratropium beyond the initial emergency department setting.

Whether magnesium sulfate plays a meaningful role in the management of the patient with severe asthma remains unclear. Magnesium exerts its bronchodilatory effects through inhibition of calcium entry into smooth muscle cells. A recent meta-analysis demonstrated that intravenous magnesium sulfate improves pulmonary function and modestly decreases the rate of hospitalization in children seeking emergency care, although, in adults with asthma, a meta-analysis of intravenous magnesium sulfate use demonstrated that a reduction in hospitalization rates occurred only with severe asthma. Intravenous magnesium sulfate is usually given over 20 to 30 minutes at reported doses of 25, 40, and 75 mg/kg, to a maximum dose of 2 g. A dose of 75 mg/kg does not produce any added benefit, and therefore dosages in this range are unnecessary. Adverse effects include flushing, nausea, and hypotension. Serious toxicities such as cardiac arrhythmias, muscle weakness, and respiratory depression are rare. Further research is needed to guide dosing recommendations and the necessity of following magnesium levels.

### Corticosteroids

Corticosteroids are indicated for any moderate to severe asthma attack and should be administered as soon as possible. The anti-inflammatory properties of corticosteroids include reduction in the number and activation of inflammatory cells, inhibition of the vascular leak induced by proinflammatory mediators, restoration of disrupted epithelium, normalization of ciliated cell:goblet cell ratio, decrease in mucus secretion, and downregulation of proinflammatory cytokine production and release. Corticosteroids also increase  $\beta$ -adrenergic receptor density on bronchial smooth muscle cells, thereby increasing  $\beta$ -agonist efficacy.

In the acute setting, corticosteroids can be administered by oral, intravenous, or intramuscular route. Although the bioavailability of oral and intravenous corticosteroids is similar, intravenous administration is preferred in status asthmaticus to ensure rapid entry

into the bloodstream and decrease the risk for aspiration. Inhaled corticosteroids, which are a mainstay of chronic asthma therapy, reduce hospitalizations in acute asthma compared with placebo, but are less efficacious than systemic corticosteroids. Commonly prescribed oral corticosteroids include dexamethasone, prednisone, and prednisolone.

Intravenous corticosteroids include methylprednisolone, hydrocortisone, and dexamethasone. For severe acute asthma, methylprednisolone is administered most often, generally given intravenously at a dose of 2 to 4 mg/kg per day divided every 6 to 12 hours, with a maximum daily dose of 60 mg. Adverse effects of corticosteroid therapy usually occur only after prolonged administration (ie, >3 weeks). In the short term, hyperglycemia, hypertension, leukocytosis, and mood and appetite changes may be encountered. A varicella vaccination and exposure history should be taken before corticosteroid therapy is initiated because of the rare but serious risk for disseminated varicella.

### Methylxanthines

Methylxanthines used in asthma include theophylline and its water-soluble salt analog, aminophylline. The primary effect of theophylline lies in phosphodiesterase inhibition, which reduces the degradation of cyclic adenosine monophosphate, resulting in dilation of airway smooth muscle. Theophylline also strengthens diaphragmatic contractility and increases respiratory drive. Although there is no longer a role for theophylline in outpatient, chronic asthma, the addition of intravenous aminophylline to  $\beta_2$ -agonists and corticosteroids in children with severe asthma improves lung function within 6 hours of treatment. However, it does not lead to any apparent reduction in symptoms or length of hospital stay and is associated with a significantly increased risk for vomiting. Because of the narrow therapeutic window of theophylline (10–20 mcg/dL), levels should be closely monitored, and use of this agent should be reserved for patients with severe asthma whose disease is not responding to maximal conventional therapy.

### Helium-Oxygen Mixtures

Helium-oxygen (heliox) mixture was used for treating upper and lower airway obstruction as early as 1935, and its use in asthma increased in the 1980s when asthma deaths began to rise. Helium gas is less dense than air and, therefore, facilitates laminar gas flow, decreases turbulent flow, and thereby reduces work, leading to easier breathing in patients with high airway resistance. Heliox is used most frequently in children with upper airway obstruction, but a randomized trial demonstrated that heliox decreased work of breathing, diminished pulsus paradoxus, and may have prevented intubation in children hospitalized with asthmaticus. Another trial demonstrated improvement in pulmonary index scores and quicker discharge from the emergency department when children were given albuterol nebulized with heliox as opposed to albuterol with oxygen alone. However, several other studies have demonstrated no benefit from heliox in the emergency department or PICU setting.

**BOX 372-1 A Stepwise Approach to the Management of Status Asthmaticus**

**Step 1:** Supportive care and prompt inhaled  $\beta$ -agonists and anticholinergics plus systemic corticosteroids

**Step 2:** Intravenous magnesium sulfate and/or intravenous aminophylline

**Step 3:** Sedation and noninvasive or invasive ventilation. Inhaled anesthetics, bronchoscopy, and extracorporeal life support may be needed for the most severe cases

There is little evidence to support the use of heliox in the context of severe acute asthma. Furthermore, any theoretical benefit of heliox is lost if less than 60% helium is in the mixture. Thus heliox may not be tolerated in patients with significant hypoxemia.

**Other Therapeutic Strategies**

A stepwise approach to management of status asthmaticus is recommended (Box 372-1). In severe, refractory cases of status asthmaticus, the use of inhalational anesthetics has been reported in the context of case reports and case series, but no randomized trials have been reported. The mechanism of action remains unknown but may involve inhibition of baseline vagal tone. In children, halothane and isoflurane have been described most extensively, and ventilation improved in most patients. However, the need for scavenging systems may pose a barrier to routine use of inhalational anesthetics outside of the operating room. Bronchoscopy with lavage and instillation of mucolytic agents is another treatment modality that has been used in severe cases in which extensive mucous plugging, bronchial casts, or both are suspected. Given the potential that bronchoscopy might worsen respiratory status, great caution should be exercised before undertaking the procedure in the context of status asthmaticus. Finally, extracorporeal life support has been used in both adults and children with life-threatening status asthmaticus, and it may be lifesaving in its ability to ameliorate severe hypoxemia, hypercarbia, or cardiovascular collapse.

**Chapter 373  
SHOCK**

Timothy Cornell, MD; Tsovinar Arutyunyan, MD;  
Joseph R. Custer, MD

The primary care pediatrician can influence the outcome of a child who presents in shock. Promptly recognizing and treating shock and following consensus guidelines and algorithms can dramatically reduce mortality and morbidity associated with shock regardless of the cause. Prompt recognition and management of shock minimizes mortality and morbidity, even if transfer to a tertiary care facility is eventually required. Simple principles of fluid and vasopressor therapy are effective regardless of the cause. The physician should be confident in treating the hemodynamic abnormalities first and establishing the cause later.

**EPIDEMIOLOGIC FACTORS**

Shock, especially septic shock and hypovolemic shock caused by diarrhea or blood loss, remains a common cause of pediatric morbidity and mortality. Severe sepsis is among the most common causes of death in infants and children in the world. In the United States, 10% of pediatric patients hospitalized for severe sepsis die during their hospitalization. Children who survive their hospitalization for severe sepsis remain at an increased risk for morbidity and mortality. Diarrhea leading to dehydration severe enough to produce shock is no longer a common cause of death in the United States, but remains a world health problem. The cost to treat shock is substantial. In a 2005 report, the national annual cost of caring for children with severe sepsis alone is estimated at \$2.3 billion.

**CLINICAL DIAGNOSIS**

Prompt recognition and early treatment can dramatically change the outcomes for pediatric patients in shock. A high index of suspicion helps identify shock in the early stages. Shock can be considered a progressive process of compensated, decompensated, and irreversible states. The diagnosis may be made in the early, compensated state by easily detectable clinical signs: tachycardia, decreased capillary refill, and altered mental status. The presence of hyperthermia or hypothermia, altered mental status, and altered perfusion (brisk in warm shock [vasodilated] or delayed in cold shock [vasoconstricted]) confirms the diagnosis of shock. Mental status is a remarkably sensitive indicator of cerebral perfusion, allowing for the

assessment of the degree of illness and response to therapy. The presence of coma or neurologic compromise implies significant brain hypoperfusion. Restoration of neurologic well-being must be a primary goal of therapy. Urine output is an additional measure of end-organ perfusion reflecting blood volume and perfusion to the kidneys. An unexplained metabolic acidosis (defined as a base deficit of  $>3.0$  mEq/L) or an increased arterial lactate (2 times the upper limit of normal) in a patient with cardiovascular symptoms confirms inadequate end-organ perfusion. Pulse rate is a reasonable proxy of cardiac output, and capillary refill is a reliable indicator of end-organ perfusion. In fact, capillary refill  $<2$  seconds is a reliable marker for therapeutic end point.

In compensated shock, all of these indicators of end-organ perfusion may be decreased, but the blood pressure (BP) will still be adequate. In the decompensated phase of shock, hypotension occurs as the child's compensatory mechanisms are exhausted. Hypotension and tachycardia are the hallmarks of severe shock in a decompensating patient. Restoration of BP and reduction of heart rate are indicators of therapeutic success. Ranges of heart rate and BP by age group can be found in Appendix C, Formulas and Reference Range Values.

Decompensated shock can quickly lead to organ failure and, ultimately, the child can enter a phase of refractory shock, which carries an increased risk of morbidity and mortality. Children with refractory shock are not responsive to aggressive volume resuscitation, catecholamines, steroids, vasopressin, or other inotropic agents.

In practice, the diagnosis of septic shock in children is confirmed with the use of simple physical assessments—mental status, pulse rate and quality, capillary refill, BP, and urine output. The phase of shock is defined by the response to treatment.

## DIAGNOSIS OF SHOCK: HISTORY

After the patient is stabilized, an accurate history may help choose additional treatments and guide appropriate referral. Infants younger than 6 weeks of age who are in shock merit special attention and a broader differential diagnosis should be considered than in older infants or children. Shock in a newborn requires attention to both acquired and congenital conditions listed in Box 373-1.

Shock in toddlers usually has a determinable, apparent cause. The physician should be aware of the propensities that are unique to this age group, especially poisonings, ingestions of medications, inhaling and swallowing of foreign bodies, trauma resulting from falls, playground and household accidents, and child abuse. The adolescent may not be forthright in volunteering an accurate history. The risk-taking behavior of the teenage years should be taken into consideration when considering the differential diagnosis in this age group. Individuals who are available to give a history may not report experimentation with drugs and alcohol. Antipsychotic medications can cause cardiovascular collapse and arrhythmias. Ingestion of antihypertensive agents and opiates in the home should also be considered in the differential diagnosis of an adolescent in shock.

### BOX 373-1 Causes of Shock in Infants

#### Cardiac

- Hypoplastic left heart syndrome
- Coarctation of the aorta
- Myocarditis
- Arrhythmia

#### Infectious

- Bacterial meningitis
- Urinary tract sepsis
- Herpes (meningitis and sepsis)
- Streptococcal sepsis

#### Metabolic

- Hypoglycemia
- Inborn errors of metabolism

#### Traumatic

- Child abuse
- Occult central nervous system hemorrhage

#### Surgical

- Bowel obstruction

#### Occult blood loss

Infants in shock present unique diagnostic challenges. Algorithmic approaches to shock diagnosis developed for children and adults may not be appropriate.

Derived from Perkin RM, Levin DL. Shock in the pediatric patient. part I. *J Pediatr*. 1982;101(3):163–169; Perkin RM, Levin DL. Shock in the pediatric patient. part II. therapy. *J Pediatr*. 1982;101(3):319–332.

In all age groups, history of travel may lead to further clues. In a child with recent exposure to pets and who has diarrhea, the possibility of *Salmonella* infection must be considered. Recent ingestion of meat and early onset of central nervous system symptoms with bloody diarrhea imply hemolytic uremic syndrome. Exposure to organophosphates should be sought if weakness is part of the presentation.

Additionally, family history is important. In a study of Danish families, the risk of death was increased 5-fold in children whose parent had died with a severe infection before the age of 50.

## CLINICAL PHYSIOLOGIC MECHANISM OF SHOCK

The underlying mechanism resulting in both symptoms and complications from shock is the inadequate delivery of oxygen to meet the metabolic demands of the body. In all shock states, oxygen delivery and blood flow to vital organs is decreased and cellular oxygen needs are increased. The signs, symptoms, and sequelae of shock are the result of inadequate perfusion of oxygen to the tissues. Delivery of oxygen to tissues is the product of the oxygen content in the blood and the cardiac output. Oxygen content depends on the percentage of hemoglobin saturated with oxygen and the dissolved amount of oxygen in the blood. Cardiac output is the product of heart rate and stroke volume, which is expressed in liters of blood flow per minute. Stroke volume is dependent on contractility (inotropy), preload (venous return to the

right heart) and afterload (arterial vascular resistance). Contractility of the myocardium is depressed by acidosis, hypoglycemia, and hypocalcemia. Epinephrine and other catecholamines act as inotropic agents, increasing contractility. Preload is the vascular volume presented to the heart during diastole, which stretches cardiac muscle, to enable optimal contraction during systole. Clinically, the central venous pressure and left atrial pressure represent preload to right and left ventricles, respectively. A patient with hypovolemia is said to have a low preload, and if blood volume is restored, then preload increases and stroke volume is increased (Figure 373-1, point a). Afterload represents the force the heart must pump against to move blood forward and is measured as systemic vascular resistance.

Children with shock may exhibit symptoms of hyperdynamic, vasodilated shock (see Figure 373-1, point c). Physiologically, cardiac output is high, peripheral vasculature is vasodilated, venous return (preload) to the heart is diminished, and systemic vascular resistance is low. On physical examination, the

patient has brisk capillary refill, is warm to the touch, and has bounding pulses, tachycardia, and a hyperdynamic precordium. Symptoms result not from low cardiac output, but rather from maldistribution of blood flow. Patients with this presentation of shock are considered to be in *warm shock*.

*Cold shock* is the opposite of *warm shock* in that children present with increased capillary refill (>2 seconds), cold extremities, and decreased pulses. *Cold shock* results from low cardiac output, constricted peripheral vasculature, decreased preload, and high systemic vascular resistance.

Heart rate is a valuable clinical sign both for diagnosis and treatment of shock in children. Infants cannot increase stroke volume as readily as adults can and rely on an increase in heart rate as a compensatory mechanism to increase blood flow to vital organs. Thus, an infant in shock whose heart rate is 2 standard deviations above normal is attempting to increase cardiac output. The return of pulse rate and BP to normal values is a valuable indicator of therapeutic success.

**Figure 373-1** The interaction of adequate volume status (preload or central venous pressure [CVP]) and contractility (cardiac output). Note the plateau in cardiac output relative to central venous filling pressure. As cardiac output reaches its maximum (in this example, at a central venous pressure of 10–12), further increase in CVP does not improve cardiac output. **Point a** represents the situation in hypovolemic shock. Here cardiac output is low, as is the CVP. The arrow indicates that as fluid administration increases preload, there is an improvement in cardiac output to **Point A**. **Point b** is a patient with a high preload (venous congestion), who would most likely have congestive signs on examination—rales, hepatomegaly, edema, and distended neck veins, with low cardiac output causing poor perfusion. This could be secondary to primary cardiogenic shock, as in myocarditis or after an ischemic event, or with myocardial dysfunction in late stages of septic shock. Evidence of poor perfusion would be obvious on examination—cold, clammy skin, prolonged capillary refill, and thready rapid peripheral pulses. The restoration of acid-base balance, glucose, calcium and magnesium levels to normal, and the addition of inotropic agents can dramatically improve function. The line from point **b** to point **B** demonstrates an improvement in output with a reduction in filling pressure. (It should be noted that, in infants, resting cardiac output is near maximum, and infants rely on increasing heart rate, whereas adults increase cardiac output by mechanisms intended to increase stroke volume.) **Point c** represents a patient who is vasodilated, with hyperdynamic cardiac output and relatively low cardiac preload. This would occur in distributive forms of shock—anaphylaxis and septic shock. This state would be reflected in the physical examination by presence of rapid capillary refill, bounding cardiac pulses, and a hyperdynamic precordium with tachycardia. (See text.)

## CLASSIFICATION OF SHOCK

The immediate goal of treatment of a patient in shock is to restore adequate tissue perfusion, and treatment should be guided by the physiologic manifestations of shock (ie, cold shock or warm shock). The physician must also determine the cause of shock, because without addressing the cause of shock, restoration of adequate tissue perfusion, if possible, will be short-lived. To assist the physician in identifying its cause, shock can be classified by the mechanisms leading to inadequate tissue perfusion—hypovolemic, cardiogenic, and distributive. Again, the pediatrician should recall that, despite complexities of cause, the early stages of shock are easy to recognize, and the treatments are straightforward.

### Hypovolemic Shock

Shock from loss of blood volume is the most common form of shock in children. Loss of fluid leads to low intravascular volume, which, in turn, decreases preload to the heart. When such losses occur over days, patients can compensate by retaining fluid and concentrating urine. Large volumes of fluid loss that occur acutely (over a few hours) lead to decompensation, represented by diminished mental status, tachycardia, oliguria, and hypotension. Two types of blood volume losses can lead to shock—hemorrhagic and nonhemorrhagic. Hemorrhagic volume loss is seen most commonly in patients following surgery or trauma, but is also commonly seen in children with gastrointestinal

bleeding. Nonhemorrhagic shock is seen in children with diarrhea, vomiting, excessive urinary losses, third spacing of intravascular fluid (peritonitis, edema), and burns.

Physical signs in hypovolemic shock occur as a result of decreased venous return to the heart, which leads to diminished cardiac output. Catecholamines are released, producing the hallmark vasoconstriction in skin, muscle, and splanchnic blood vessels. The renin-angiotensin system is activated, promoting the retention of salt and water. Fluid resuscitation restores preload, increasing cardiac output and leading to improved tissue perfusion and resolution of symptoms. Physical signs in nonhemorrhagic patients can be helpful to estimate the percentage of body fluid losses (Table 373-1).

In hemorrhagic shock, physical findings correlate to the amount of blood loss (see Table 373-2).

### Cardiogenic Shock

Cardiac shock can be caused by mechanical obstruction or muscle (pump) failure. The heart can fail as a mechanical pump from a variety of causes Box 373-2.

Patients with cardiac failure have low cardiac output because of decreased contractility and low stroke volume. The most common causes of obstructive cardiogenic shock involve narrowing of the left ventricular outflow tract Box 373-3.

Rarely, obstruction of forward flow of blood through the heart can be caused by rapid expansion of fluid in the pericardium or pleural spaces, leading to tamponade physiology. In addition to the signs and symptoms of shock discussed earlier, patients with cardiogenic shock usually exhibit distended neck veins from increased jugular venous pressure, along with evidence of venous congestion (hepatomegaly).

**Table 373-1**

#### Physical Signs in Dehydration

PERCENTAGE OF DEHYDRATION	PHYSICAL SIGNS
5% (mild)	Dry skin, mild tachycardia, concentrated urine
10% (moderate)	Lethargy, poor perfusion
15% (severe)	Obtundation, tachycardia, hypotension, very poor perfusion to skin

**Table 373-2**

#### Physical and Vital Signs in Hemorrhagic Shock

BLOOD VOLUME LOST (%)	SIGNS
<15%	Minimal tachycardia, normal respiratory rate, blood pressure, and capillary refill
15%–30%	Tachycardia, tachypnea, decreased pulse pressure, normal systolic pressure, prolonged capillary refill, anxiety
30%–40%	Hypotension, decreased urine output, mental status changes
>40%	Hypotension, loss of consciousness

#### BOX 373-2 Pump Failure

- Arrhythmia
- Hypoplastic left heart syndrome
- Decreased contractility acquired in sepsis syndrome or shock from any cause
- Myocardiopathy
- Myocarditis
- Anomalous coronary artery
- Cardiac contusion
- Storage disease—glycogen storage disease

#### BOX 373-3 Causes of Obstructive Cardiogenic Shock

- Tamponade (air, blood, or effusion)
- Coarctation of the aorta
- Aortic valve stenosis or atresia
- Hypoplastic left heart syndrome

### Septic Shock

Septic shock is the most common and certainly best studied cause of shock the primary care pediatrician will encounter. The causes of bacterial septic shock have changed since vaccination against *Haemophilus influenzae* type b was instituted in 1988. If sepsis in the immunocompromised patient is excluded, staphylococci and streptococci are the most commonly encountered bacterial causes of sepsis. Patients with infections caused by *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Candida* species, and *Streptococcus pyogenes* have higher mortality rates compared to patients with infections caused by coagulase-negative *Staphylococcus* and *Acinetobacter* species.

Children and adults exhibit developmental differences in the hemodynamic response to sepsis. In adults, mortality is caused by a vasopressor and volume resistant state characterized as vasomotor paralysis. Myocardial dysfunction is common in adults, but cardiac output is maintained by tachycardia and ventricular dilatation.

In pediatric septic shock, low cardiac output, not vasodilatation, is associated with mortality. In children, oxygen delivery is the major determinant of oxygen consumption, and survival correlates with the restoration of adequate cardiac output and oxygen delivery.

A large number of children with septic shock have absolute or relative adrenal insufficiency. This state results from inadequate adrenal corticosteroid release despite a very stressful condition. Infants and children at risk include those with septic shock and purpura, those with known or suggested adrenal abnormalities, and children who have received a therapeutic course of steroids in the 6 months before the onset of sepsis. In patients whose shock state is refractory to volume, dopamine or dobutamine, and the addition of epinephrine or norepinephrine (catecholamine-resistant shock), empirically initiating stress-dose steroids would be reasonable for those at risk for adrenal insufficiency.

Those children who remain in shock despite aggressive fluid resuscitation, cortisol supplementation, the addition of 2 catecholamine drugs, and normalization of acid-base, glucose, and calcium homeostasis are characterized to be in refractory shock; aggressive therapies, including extracorporeal life support, should be considered.

### Distributive Shock

Distributive shock disorders result from a dysfunction of vasomotor control resulting in maldistribution of blood flow and oxygen to tissue. Anaphylaxis and spinal cord injury are the 2 types most likely to be encountered in primary care. Cardiac output may be normal or increased. These patients lose sympathetic control of the vascular system, which reduces peripheral vascular tone resulting in pooling of blood in the periphery, which, in turn, leads to decreased venous return to the heart.

In anaphylactic shock, the inciting agent should be removed if possible. These patients uniformly respond well to volume administration, epinephrine infusion, antihistamines that include an H<sub>2</sub>-receptor blocker, and steroid therapy.

### TREATMENT

Three basic principles that should guide the therapy of a patient in shock are prompt recognition of a patient in shock, rapid restoration of systemic and regional perfusion to prevent ongoing shock and cellular injury, and correction of the cause of shock.

The most important predictor of outcome is appropriate resuscitation and reversal of shock within 75 minutes of recognition. Han and colleagues documented increased survival and decreased morbidity in a group of infants and children in shock treated by community physicians. Children treated following the American College of Critical Care Medicine *Pediatric Advanced Life Support* (ACCM-PALS) practice parameters for hemodynamic support of pediatric patients had improved survival compared to children who did not receive treatment following the guidelines (see Appendix A, Pediatric Cardiopulmonary Resuscitation).

The guidelines for diagnosis, care, and treatment of infants and children are based on a time line from recognition of shock and are the patient's response to each therapy. Key features of the guidelines include:

5 minutes:

- Recognize decreased mental status and poor perfusion. Secure the airway and provide bag-mask ventilation (ie, bag-mask the patient). Start to establish venous access upon recognition of shock. Peripheral intravenous or intraosseous access is appropriate for initial resuscitation. Provide intravenous fluid (20 mL/kg) once venous access is established.
- Begin monitoring the child (see monitoring guidance in Box 373-4).

15 minutes:

- Administer intravenous fluids within the first 15 minutes. The volume of each fluid bolus should be 20 mL/kg and should be administered in less than 5 minutes. Fluid needs can exceed 60 mL/kg of body weight.
- Begin broad-spectrum antibiotics as soon as possible.

#### BOX 373-4 Monitoring the Child in Shock in the Primary Care Setting

- Capillary refill
- Documentation of mental status
- Pulse oximetry
- Continuous electrocardiogram
- Blood pressure (cuff)
- Temperature
- Urine output
- Glucose and ionized calcium level
- Serum hemoglobin or hematocrit
- Hepatomegaly is a reliable indicator of volume overload and cardiac compromise

#### Successful resuscitation is recognized by

- Return of pulse rate to normal
- Improvement in mental status
- Return of capillary refill
- Improvement in acid-base status

- 30 minutes (15 minutes after fluid therapy begins):
- For children who do not immediately respond to fluid administration (15 minutes from beginning of fluid therapy) as indicated by improved end-organ perfusion, peripheral low-dose dopamine or epinephrine should be initiated through a second peripheral intravenous or intraosseous catheter until a central venous line is placed. Administration of vasopressors should not be delayed pending placement of the central venous line.
  - Children who do not respond to dopamine infusion up to 10 mcg/kg/min and fluid resuscitation (at least 60 mL/kg) have dopamine–fluid refractory shock. Institute infusion of epinephrine (0.05–0.3 mcg/kg/min) for cold shock or norepinephrine (0.05–0.3 mcg/kg/min) for warm shock. Glucose, serum hemoglobin or hematocrit, acid-base homeostasis, and ionized calcium should be monitored and restored to normal values.
- 60 minutes:
- Children who do not respond to fluid and an infusion of 2 catecholamine agents within 60 minutes have catecholamine-resistant shock, and adrenal insufficiency should be considered.
  - Refer to a tertiary care pediatric intensive care unit if children do not respond to fluid administration and to dopamine and epinephrine or norepinephrine infusions. These children require diagnostic evaluation for cardiac function and will require central venous access, echocardiography, and mixed venous oxygen saturation monitoring.

Treatment of shock, especially in primary care settings, is based on restoring adequate circulating blood volume, thereby achieving adequate delivery of glucose and oxygen to all tissues. Drugs and fluids for the treatment of shock are listed in Table 373-3. Monitoring and documenting the patient's response to each intervention is essential. Patients who develop organ failure have a markedly worse prognosis in shock. Specific definitions of organ failure are listed in Box 373-5.

Early volume resuscitation and vasopressor therapy are always indicated in the treatment of shock. Low-dose vasopressors may be initiated peripherally and should not be delayed until central venous access is established. Hepatomegaly is a reliable clinical indicator of volume overload. In children who develop hepatomegaly, but remain hemodynamically unstable, cardiac or renal failure must be considered.

Physicians should remember that fluid requirements in shock may exceed 60 mL/kg, and a common error is to give too little fluid too slowly. Rather than fearing fluid overload and thus undertreating the vast majority of patients, the physician should gauge the patient's response to fluid administration. Assessment of the patient's vital signs, mental status, and urine output should take place after each rapid 20 mL/kg fluid bolus. No conclusive data are found in the literature proving superiority of one fluid over another. Commonly used solutions are normal saline, lactated Ringer solution, or 5% albumin. The volume of the bolus should be 20 mL/kg of body weight.

Central venous access should be established in fluid/dopamine refractory patients once they are stabilized. Patients who remain tachycardic with poor capillary refill and inadequate urine output (<0.5 mL/kg/hr) after 60 mL/kg of fluid and the addition of 2 vasopressors are in catecholamine-resistant shock. Patients in this decompensated state will require referral to a tertiary pediatric intensive care unit for further diagnosis and treatment.

All patients in shock should immediately be given 100% oxygen. The oxygen saturations should be monitored continuously with a pulse oximeter. However, physicians need to appreciate that normal oxygen saturation on a pulse oximeter does not imply adequate oxygen tissue delivery. Because normal oxygen saturation does not reflect adequate oxygen content, the hemoglobin (the carrying vehicle for oxygen) should be measured and oxygen content should be determined. Blood transfusions may be necessary to ensure adequate oxygen delivery. If the circulation is compromised and cardiac output falls, then oxygen delivery to tissues will be compromised. The outcome for children in shock is dependent on adequate oxygen delivery and adequate oxygen delivery is associated with improved survival.

Oxygen delivery is the product of oxygen content and cardiac output. Oxygen content =  $1.36 \times$  the percentage of saturation  $\times$  hemoglobin (in grams) and is expressed as milliliters of oxygen per 100 mL of blood. In healthy children, oxygen consumption is 25% of oxygen delivery. In shock states, oxygen consumption may increase simultaneously with inadequate cardiac output, leading to inadequate tissue oxygenation. If lung disease is present or hypoventilation occurs, then hemoglobin is

**Table 373-3** Drugs and Fluids Used in the Treatment of Shock in Children and Infants

MEDICATIONS AND FLUIDS FOR TREATMENT OF SHOCK	DOSES
<b>FLUIDS</b>	
Normal saline	20–80 mL/kg
Albumin 5%	20–80 mL/kg
<b>MEDICATIONS</b>	
Dopamine	5–20 mcg/kg/min
Epinephrine	0.01–0.2 mcg/kg/min
Norepinephrine	0.01–0.2 mcg/kg/min
Dobutamine	5–20 mcg/kg/min
Milrinone	0.3–0.7 mcg/kg/min
Hydrocortisone (vasopressor resistant)	2 mg/kg/dose
Vasopressin	0.0003 units/kg/min to 0.01 units/kg/min
Calcium chloride (10%)	20 mg/kg

**BOX 373-5 Definitions of Organ Failure for Pediatric Patients in Septic Shock****CARDIOVASCULAR DYSFUNCTION**

Despite administration of isotonic intravenous fluid bolus  $\geq 40$  mL/kg in 1 hr,

- Decrease in blood pressure (BP) levels (hypotension): 2 standard deviations below normal for age

OR

- Need for vasoactive drug to maintain BP in normal range (dopamine  $> 5$  mcg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose)

OR

- 2 of the following:

Unexplained metabolic acidosis: Base deficit  $> 5.0$  mEq/L

Increased arterial lactate:  $> 2$  times upper limit of normal

Oliguria: Urine output:  $< 1$  cc/kg/hr

Prolonged capillary refill:  $> 5$  sec

Core to peripheral temperature gap:  $> 3^{\circ}\text{C}$

**RESPIRATORY**

- $\text{PAO}_2/\text{FIO}_2$ :  $< 300$  in absence of cyanotic heart disease or pre-existing lung disease

OR

- $\text{PaCO}_2$ :  $> 65$  torr or 20 mm Hg over baseline  $\text{PaCO}_2$

OR

- Proven need or  $> 50\%$   $\text{FIO}_2$  to maintain saturation  $\geq 92\%$

OR

- Need for nonelective invasive or noninvasive mechanical ventilation

**NEUROLOGIC**

- Glasgow Coma Score:  $\leq 11$

OR

- Acute change in mental status with a decrease in Glasgow Coma Score of  $\geq 3$  points from abnormal baseline

**HEMATOLOGIC**

- Platelet count:  $< 100/\text{mL}$  or a decline of 50% in platelet count from highest value recorded over the last 3 days (for patients with chronic hematologic disease or cancer)

OR

- International normalized ratio:  $> 2$

**RENAL**

- Serum creatinine:  $\geq 2$  times upper limit of normal for age, or 2-fold increase in baseline creatinine level

**HEPATIC**

- Total bilirubin:  $\geq 4$  mg/dL (not applicable for newborn)

OR

- Alanine aminotransferase (ALT): 2 times upper limit of normal for age

Each additional organ failure increases the risk of death.

From Goldstein B, Giroir B, Randolph A, et al. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. *Pediatr Crit Care Med*. 2005;6:2–8. Reprinted with permission from Lippincott Williams & Wilkins.

desaturated and oxygen delivery is compromised further. Initiation of mechanical ventilation may be necessary, both to decrease oxygen consumption by supporting the work of breathing and to optimize oxygen delivery.

Arterial lactic acidosis (normal is  $< 2$  mmol/L) or an increasing base deficit ( $> 3$  mEq) document inadequate perfusion. The effects of restoring the pH to over 7.25 are important: myocardial contractility is enhanced, sensitivity to catecholamines is improved, and potassium is returned to the intracellular space. Sodium bicarbonate (2 mEq/kg) may be required to improve

blood pH to over 7.25 and serum bicarbonate levels to more than 15 mEq/dL. Any remaining base deficit may be corrected by using the following guide:  $0.3 \times \text{body weight in kilograms} \times \text{base deficit} = \text{milliequivalents of sodium bicarbonate}$ .

Other metabolic derangements should also be corrected in children in shock, especially low levels of glucose and calcium. Children consume glucose at a faster rate than do adolescents and adults. In infants and toddlers, glucose levels should be considered a vital sign, and blood glucose needs to be added to

maintain adequate blood glucose levels. Glucose replacement is crucial, especially in very young patients. Glucose should be maintained at over 60 mg/dL. Hypocalcemia is also common in children with shock. Total calcium measurements do not correlate with measurements of the biologically important ionized calcium. Restoring ionized calcium to normal levels improves myocardial contractility, especially in neonates and infants.

### Vasopressor Drugs

Catecholamines do not replace adequate, aggressive, and early fluid administration as the initial treatment for shock. Dopamine, norepinephrine, epinephrine, and dobutamine are the drugs of choice in the early treatment of shock. Most cases of shock encountered in primary care are likely to require only fluid resuscitation. A vasoactive drug should be infused continuously with a calibrated infusion pump, and continuous heart rate and BP monitoring are required.

The physiologic effects of catecholamines are based on their relative effects on the  $\alpha$ - or  $\beta$ -adrenergic receptor. The  $\alpha$ -receptor produces vasoconstriction and, when stimulated, increases BP.  $\beta$ -agonists have 2 receptor sites:  $\beta$ -1 receptors stimulate heart rate and cardiac muscle contractility;  $\beta$ -2 receptors are present in bronchial and arteriole smooth muscles, and these muscles relax when stimulated. Dopamine has primarily  $\alpha$ -adrenergic and  $\beta$ -1 adrenergic effects. Epinephrine has predominantly  $\beta$ -1 adrenergic effects, and norepinephrine has predominantly  $\alpha$ -adrenergic effects.

Dopamine is the initial drug of choice and is administered at doses of 5 to 10 mcg/kg/min and titrated to effect. The  $\alpha$ -adrenergic effects predominate with vasoconstriction and reduced peripheral perfusion. Patients who do not respond to fluid resuscitation of 60 mL/kg and 10 mcg/kg/min of dopamine are in a state referred to as dopamine–fluid resistant shock and require addition of epinephrine (cold shock) or norepinephrine (warm shock).

Children who are thought to have low cardiac output may benefit from dobutamine. Dobutamine differs from dopamine because of its enhanced inotropic effect with less chronotropic effect than dopamine; it also has less effect on systemic vascular resistance. In some circumstances, especially shock after hypoxemic-ischemic injury, epinephrine or dobutamine may be preferred because dopamine may precipitate tachyarrhythmias and increase myocardial oxygen consumption.

Hydrocortisone is indicated in limited circumstances. Children with anaphylaxis, those with known or suggested adrenal abnormalities, and children who have received a therapeutic course of steroids for chronic illness in the 6 months before the onset of shock will require stress-dose steroids at 1 to 2 mg/kg of hydrocortisone. Children in refractory septic shock are, by definition, unresponsive to volume resuscitation, the addition of 2 catecholamine drugs, and normalization of acid-base, glucose, and calcium homeostasis; they may respond to hydrocortisone.

In select situations, and in tertiary care settings only, the use of vasodilator drugs (nitroprusside, milrinone, nitroglycerin) may be beneficial in reducing afterload when high peripheral vascular resistance and low cardiac output is encountered. This therapy optimizes

### BOX 373-6 Sample Case Report

A 3-year-old child exhibits a lung contusion and splenic hematoma. The hemoglobin is 10, heart rate is 180 beats per minute, systolic blood pressure is 80 mm Hg, and arterial saturation of oxygen by pulse oximetry is 90%. On examination, the patient is difficult to rouse, tachycardic, and has capillary refill >4 seconds. Evidence is ample that the patient's cardiac output is compromised because heart rate is elevated, perfusion is inadequate, and mental status is depressed.

The patient's oxygen content is  $(1.36 \times \text{serum hemoglobin} \times \text{arterial saturation})$  or  $1.36 \times 10 \times 0.90 = 12.3$  mL of oxygen/100 mL blood, whereas normal oxygen content is  $1.36 \times 13 \times 100 = 17.68$  mL oxygen/100 mL blood. Transfusion of red blood cells to reach a hemoglobin count of 13 thus increases oxygen content of the patient's arterial blood nearly 50% (from 12.3 to 17.8 mL/100 mL blood).

myocardial contractility and improves cardiac output, but requires sophisticated monitoring, including pulmonary arterial oximetry, cardiac output measurement, and pulmonary vascular pressure catheters.

Vasopressin is an endogenous hormone that works on the pituitary gland to release adrenocorticotrophic hormone (ACTH) and acts as an antidiuretic by its direct effect on renal tubules. Currently, its use is limited to tertiary care centers and is indicated for warm shock with low BP. Extracorporeal membrane oxygenation (ECMO) is considered for children in refractory septic shock in tertiary institutions. (See Table 373-3.)

### SEQUELAE OF SHOCK

Several organ systems may be affected by shock (see Box 373-5). A common form of hypoxemic respiratory failure known as acute respiratory distress syndrome occurs 24 to 48 hours after presentation of shock. The child becomes dyspneic and hypoxemic, with a P/F (partial pressure of oxygen/fraction of inspired oxygen) ratio of less than 200. Physical examination reveals rales and tachypnea; a chest radiograph reveals diffuse pulmonary infiltrates. The interstitial edema that develops seems to be caused by a capillary leak syndrome. This complication is life-threatening, and the patient should be referred to a tertiary intensive care unit. Mechanical ventilation and positive end-expiratory pressure, high-frequency oscillatory ventilation, or extracorporeal membrane oxygenation support may be required.

Myocardial depression is commonly encountered in septic shock. Inadequate perfusion, increased work, and distension of cardiac muscle in the presence of inflammatory mediators affect contractility and may lead to decrease in cardiac output.

Renal failure, especially acute tubular necrosis, is common. A serum creatinine more than twice normal for age is diagnostic. Renal failure is suggested when the urine output is under 0.5 mL/kg/hr, despite adequate restoration of blood volume.

Unrecognized renal failure will increase the mortality resulting from shock. Serum levels of drugs in the blood become uncertain. Doses of antibiotics, sedatives, and analgesics must be monitored carefully, following blood

levels in serum whenever possible. Fluid therapy must be titrated carefully to insensible fluid loss replacement; otherwise congestive heart failure will result. Anuria or oliguria complicating shock requires referral or consultation with a nephrologist or intensivist.

The central nervous system is most susceptible to inadequate oxygen delivery. A child may suffer significant neurologic impairment, although other organs are spared. Early central nervous system signs of shock include delirium, irritability, confusion, and coma. Signs of increased intracranial pressure are usually delayed 24 to 72 hours after a hypoxemic-ischemic insult. A Glasgow coma score of less than 11 or a decrease of 3 points from baseline are diagnostic of central nervous system compromise.

Liver function may become impaired as a result of inadequate perfusion. Bilirubin levels of more than 4 mg/dL and alanine aminotransferase levels greater than twice normal are diagnostic of hepatic failure. Clotting factors may be diminished. In septic shock, liver perfusion may be adequate, but bacteria or toxins may damage hepatic cells. Liver failure is usually transient.

Immune dysfunction can also occur following shock, leading to a state of immunoparalysis. Pediatric patients identified as immunoparalyzed are at increased risk for development of nosocomial infections.

## SUMMARY

Shock in the pediatric setting is a relatively common emergency. The diagnosis of shock is clinical, based on mental status, tachycardia, and peripheral perfusion. Early treatment does not require sophisticated monitors, central venous catheters, or invasive monitoring. Community caregivers can make a significant difference in the outcome of children in shock by recognizing shock early and following established guidelines for the early treatment of shock.

## Chapter 374 STATUS EPILEPTICUS

Sarah M. Roddy, MD; Margaret C. McBride, MD

*Status epilepticus* is defined by the World Health Organization as “a condition characterized by an epileptic seizure that is sufficiently prolonged or repeated at sufficiently brief intervals as to produce an unvarying and enduring epileptic condition.” In 1993 the International

League Against Epilepsy further defined status epilepticus as any seizure that continues for 30 minutes or intermittent seizures lasting 30 minutes or longer in which the person does not regain consciousness between the episodes. Data have suggested that earlier treatment decreases the likelihood that status epilepticus will become refractory. It is now widely accepted that, if available, treatment for status should begin if a seizure has not stopped within 5 minutes.

Status epilepticus can be classified in terms of the type of seizure. *Generalized convulsive status epilepticus* is the most common and easily recognized type in children. The seizure activity usually is tonic-clonic or clonic and is less often tonic or myoclonic. In *focal motor status epilepticus*, also known as *epilepsia partialis continua*, focal seizure activity is prolonged and restricted to one side of the body without loss of consciousness. *Nonconvulsive status epilepticus* includes absence status and complex partial status and exhibits as a confused, drowsy, or obtunded state in which the patient may seem to move in slow motion or may be motionless, resulting from continuing or repetitive generalized or focal discharges (see Chapter 327, Seizure Disorders).

## INCIDENCE

The incidence of status epilepticus in patients who have epilepsy ranges from 4% to 16%. Its frequency is highest in the younger age groups. Up to 70% of children with epilepsy beginning before the age of 1 year experience status epilepticus. Infants and children also are far more likely than adults to have status epilepticus as the manifestation of their first seizure: roughly 10% of children with seizures have initial presentation as status epilepticus. Status epilepticus accounts for 5% of all febrile seizures in children.

## ETIOLOGY

In approximately 32% of cases, status epilepticus is provoked solely by fever. Remote symptomatic status epilepticus occurs in patients with a history of a central nervous system abnormality known to be associated with increased risk for seizure. This group accounts for another 18% of cases of status in children; many of these affected patients have cerebral palsy or intellectual disability. Another 29% are cryptogenic—presumed to be related to an underlying factor, but the factor has not been identified. Acute symptomatic status epilepticus accounts for another 17% of cases and is an expression of an encephalopathy or brain injury occurring within a week of status. Causes in this group include central nervous system or meningeal infection, electrolyte disturbance, low levels of antiepileptic drugs, and drug ingestion. Approximately 4% of cases of status are idiopathic. The cause in a small percentage of cases is a progressive encephalopathy such as in neurodegenerative diseases. It is important to determine the cause of status epilepticus through history, physical examination, laboratory investigations, neuroimaging, and electroencephalography (EEG) in order to guide treatment.

## HISTORY

A history should be obtained from an accompanying family member and should include any history of

previous seizures, chronic and recent medication use, intercurrent illness, head trauma, how an infant's formula is mixed, medications available in the home, and details of the onset of status epilepticus. Family history of seizures and previous history of signs or symptoms of underlying neurologic disorder are also important.

### PHYSICAL EXAMINATION

At physical examination, vital signs, fever, and any evidence of head trauma, increased intracranial pressure, or infection should be noted. Additionally, the examiner should look carefully for any evidence of asymmetry in cranial nerves, muscle bulk and tone, movement, and deep tendon reflexes.

### LABORATORY EVALUATION

A rapid bedside blood glucose level should be obtained immediately, and if the glucose level is less than 60 mg/dL, give 2.5 mL/kg of 10% dextrose as a bolus followed by infusion of 5 to 8 mg/kg/minute in infants and 3 to 5 mg/kg/minute in older children. Blood samples should be drawn to assess levels of electrolytes, glucose, blood urea nitrogen, and calcium; complete blood count; and possibly liver and renal function. If the patient was previously treated for seizures, levels of the prescribed anticonvulsant medication should be determined. If the cause of status is not obvious on initial history and examination, a urine sample should be assessed for drugs of abuse, and a blood sample should be taken for assessing levels of medications available in the home that may be associated with seizures, especially bupropion hydrochloride. Blood cultures and evaluation of cerebrospinal fluid may be indicated in febrile status epilepticus but are rarely helpful in afebrile status.

### ELECTROENCEPHALOGRAPHY

Baseline EEG, after treatment, is important for all children presenting in status epilepticus as their first seizure but is rarely useful in children with a history of seizures and previous EEG. Continuous EEG monitoring is important in children with status epilepticus if they have not returned to their baseline within 30 minutes of the cessation of visible signs of status. Up to 25% of children with convulsive status epilepticus have nonconvulsive status epilepticus persisting after cessation of the convulsion, and the incidence increases to 45% if the convulsive status epilepticus was refractory to initial treatment.

### Imaging Studies

Neuroimaging is important in all children who present in status epilepticus as their first seizure unless a previous neuroimaging study has defined a brain lesion and no new insults are expected. Head magnetic resonance imaging (MRI) is preferable because of the lack of radiation to the child and the detail MRI provides for small lesions and white matter changes. Head computed tomography (CT) is often more readily available and typically does not require sedation. CT is a good study to assess for the possibility of intracranial bleeding. Studies indicate that 13% to 32% of

children presenting with status epilepticus as their first seizure show abnormalities on neuroimaging.

### TREATMENT

The objective in treating convulsive status epilepticus is to prevent mortality and morbidity by maintaining vital functions, identifying and correcting any precipitating factors, and controlling seizure activity. Box 374-1 outlines a plan for treatment. Most episodes of status epilepticus are controlled by 1 or more of the drugs named in Box 374-1.

Nonconvulsive status epilepticus and epilepsy partialis continua require prompt treatment, but slightly less urgency exists because these seizures do not alter the body's homeostatic mechanisms to the degree that convulsive status epilepticus does. Convulsive status epilepticus is considered a medical emergency because it is life threatening and is sometimes followed by severe neurologic sequelae. The longer convulsive status epilepticus continues or the higher the fever associated with it, the more resistant it is to therapy and the greater the incidences of mortality and morbidity. Studies have shown that continued seizure activity for more than 60 minutes results in permanent cell damage, even in ventilated animals whose metabolic parameters are kept in the normal range. Neurologic sequelae from status epilepticus include intellectual impairment and motor dysfunction.

If the history or physical examination suggests a central nervous system infection, then antibiotics should be administered immediately and a lumbar puncture performed as soon as seizure activity has been controlled and the presence of significantly increased intracranial pressure has been excluded because of the risk for herniation. Because neurologic sequelae of status epilepticus can result from precipitating factors such as hypoxia, hypotension, and acidosis, immediate attention should be given to the respiratory and cardiovascular status of the child. If the patient is febrile, then priority is given to reducing body temperature because of the synergy between fever and status epilepticus in producing brain damage.

After seizure activity is controlled, management should be directed toward preventing recurrence of seizures, including maintenance anticonvulsant therapy. The appropriate duration of therapy after an initial episode of idiopathic status epilepticus is not clear. For a child who has had generalized convulsive status epilepticus, consideration should be given to prescribing nasal/buccal midazolam or rectal diazepam gel to be administered by caregivers at home for seizures lasting longer than 5 minutes. Epilepsy occurs in one-third of children after an initial presentation of status epilepticus. Status epilepticus recurs in 15% to 20% of children; the recurrence is about 4% in idiopathic or febrile status and up to 88% in symptomatic status.

### OUTCOME

Over the past 25 years, morbidity and mortality from status epilepticus have declined, probably because of the availability of benzodiazepines, better access to medical care, and more aggressive treatment by emergency medical technicians. In children with idiopathic or febrile status epilepticus, less than 5% develop new

**BOX 374-1 Treatment of Status Epilepticus**

- Assess and support cardiopulmonary function by making sure that the airway is clear and the patient is in a good position for airway patency and avoiding aspiration—generally on the left side. Air exchange in the lungs during vigorous tonic-clonic status occurs because of recurrent rib cage and diaphragmatic contraction rather than actual breathing, or a patient may be breathing on top of the seizure movements. It may be helpful to increase the percentage of oxygen in the air that is being exchanged by applying a mask with oxygen. Assess blood pressure and pulse and consider applying electrocardiogram leads. Provide respiratory support and cardiac stimulation (cardiopulmonary resuscitation) as necessary.
- Establish an intravenous or intraosseous access and obtain blood samples for bedside glucose determination, electrolytes, blood urea nitrogen, calcium, complete blood count, and anticonvulsant medication levels. If the rapid glucose determination is less than 60 mg/dL, give 2.5 mL/kg of 10% dextrose as a bolus followed by infusion of 5 to 8 mg/kg/minute in infants and 3 to 5 mg/kg/minute in older children. Blood glucose should be reassessed at frequent intervals until stable in the normal range, and significant hyperglycemia should be avoided.
- As the first 2 steps are being implemented, a member of the emergency team should obtain a history while another does a physical examination.
- If the patient is febrile, especially with fever above 102°F, attention should be given to aggressively cooling the child with rectal antipyretics and mechanically with ice, wet towels, or a cooling blanket. This is important because it is harder to stop status in a febrile patient, and the combination of status and fever doubly increases the metabolic needs of the brain compared with either alone. Therefore, with the combination of prolonged fever and status epilepticus, brain damage is more likely.
- Administer anticonvulsant drugs in the following order until seizure activity is controlled:
  - Lorazepam should be the initial anticonvulsant administered intravenously at a dose of 0.1 mg/kg (maximum 4 mg) over 2 minutes; a dose of 0.05 to 0.1 mg/kg may be repeated every 5 minutes as necessary up to a maximum of 0.5 mg/kg, but not over 10 mg total. Lorazepam has a 6- to 8-hour duration of effect. Therefore, unlike diazepam, another anticonvulsant need not be administered right away if the status epilepticus has stopped.
  - If lorazepam is not available, then diazepam should be administered intravenously at a dose of 0.1 to 0.2 mg/kg (maximum 10 mg) by pushing one-half the dose over 1 minute and the remainder at 1 mg/minute. A dose of 0.1 mg/kg may be repeated in 5 minutes if necessary. Because of diazepam's short duration of anticonvulsant effect, another anticonvulsant such as fosphenytoin must be administered immediately, even if the status epilepticus has stopped.
  - If intravenous access is not available, the patient should be given 0.2 to 0.3 mg/kg (up to 10 mg) of intranasal or intrabuccal midazolam, using the more concentrated solution of 5 mg/mL for better absorption. Rectal diazepam gel at 0.3 to 0.5 mg/kg may also be used as an alternative. Intranasal/intrabuccal midazolam acts a little faster and is easier to administer than rectal diazepam. It is helpful to split the intranasal/intrabuccal dose between the 2 nostrils or cheeks for better absorption.
- If the patient is known to be receiving phenytoin on a chronic basis, then 5 to 8 mg/kg phenytoin equivalents of fosphenytoin should be administered as the initial anticonvulsant. Fosphenytoin is the water-soluble prodrug of phenytoin with a more neutral pH value. If fosphenytoin is not available, intravenous phenytoin may be used carefully as one-fourth of the 15- to 20-mg/kg dose administered during the first 2 minutes, and the remaining at a rate of 1 mg/kg/minute (maximal rate of 50 mg/minute).
- If status epilepticus continues and the patient is not receiving phenytoin, then administer fosphenytoin as 20 mg/kg of phenytoin equivalents to a total maximum dose of 1,000 mg. Intravenous fosphenytoin may be administered at 3 mg/kg/minute (maximal rate of 150 mg/minute). Monitor the heart rate and slow the rate of fosphenytoin infusion if bradycardia occurs. Intravenous fosphenytoin is superior to intravenous phenytoin because it will not cause vein and skin sclerosis if extravasated from the small veins of children. If intravenous access is not available, the loading dose of fosphenytoin—not phenytoin—may be given intramuscularly. If seizure activity continues despite a full loading dose of fosphenytoin, then correction of presumed underlying acidosis with sodium bicarbonate (0.25 to 0.5 mEq/kg) may be indicated.
- If status epilepticus continues, then 1 of the following 3 drugs may be given intravenously. If the attempted medication is not effective, then another may be tried.
  - Phenobarbital is given in a dose of 20 mg/kg up to a total of 800 mg. Administer this amount over 15 minutes, monitoring respirations and blood pressure, especially if the patient has been treated with a benzodiazepine.
  - Levetiracetam may be given in a dose of 30 to 50 mg/kg over 5 to 15 minutes. Its side effects include sedation but less respiratory suppression than phenobarbital.
  - Valproic acid is administered as 25 mg/kg over 8 to 10 minutes. Valproate is not a good choice in a patient with liver dysfunction but has the advantage of less sedation and lack of respiratory depression.
- Generally by the time a third intravenous drug has been given, especially if phenobarbital has been added to full doses of lorazepam, the patient will require intubation, particularly before further treatment such as midazolam or pentobarbital infusion is given. If a muscle relaxant is used for intubation, it must be short acting, and treatment of the status should continue even though the convulsive

**BOX 374-1 Treatment of Status Epilepticus—cont'd**

movements are not seen clinically. Continuous EEG monitoring is strongly indicated if muscle relaxant therapy persists or the patient has not returned to baseline within 30 minutes of the end of convulsive status epilepticus. If seizure activity of unknown cause persists, 100 mg of pyridoxine (vitamin B<sub>6</sub>) may be given to treat the rare patient with pyridoxine dependency or insufficiency, preferably with an EEG running to help assess its effect.

- If seizure activity still persists, it is considered to be refractory status epilepticus, and it is important to consult a neurologist and/or intensivist to determine the need for other anticonvulsants, general anesthesia, or induction of pentobarbital, diazepam, midazolam, or propofol coma. A neurologist will be needed to pursue continuous EEG monitoring.

neurologic dysfunction. Mortality in children attributable to status epilepticus is 2% to 6%, with most deaths caused by the illness that precipitated the seizure. Morbidity (epilepsy, cognitive deterioration, behavioral problems, motor syndromes including spasticity, extrapyramidal syndromes, and cerebellar syndromes) is reported in up to 15% of children, is often related to the cause of the status, and is more common in younger children.

**WHEN TO REFER**

- When seizure activity cannot be controlled
- After seizure activity is controlled, if a history of previous afebrile seizures is present and a physician with experience in prescribing maintenance anticonvulsant medication is not available
- If the patient does not return to baseline within 30 minutes of the cessation of motor status and continuous EEG monitoring is not available

**WHEN TO ADMIT**

- Always for a child whose status epilepticus was not quickly controlled
- Always for a child who is unresponsive after status epilepticus, or not back to baseline in 30 minutes
- For any child who may have acute symptomatic status

## Chapter 375

# THERMAL INJURIES

Robert L. Sheridan, MD

Burns are common, with nearly 100,000 children per year treated for burns in emergency rooms. Most pediatricians need to deal with burns periodically. Expectations for the functional and aesthetic quality of burn outcomes have become very high. In recent years, survival has improved significantly for children with serious burns. The long-term outcome for children, even with severe burns, is generally good when they participate in a burn aftercare program. Coincident with increasing survival and improving outcome quality has been the evolution of the burn center paradigm, in which all aspects of necessary care are coordinated in a single program.

**EPIDEMIOLOGIC FEATURES**

Approximately 70% of pediatric burns are caused by hot liquid. In older children and young working adults, flame, electrical, and chemical injuries become more common. Approximately 20% of burns in young children involve abuse or neglect. Organized burn prevention efforts have met with mixed success when based on public education, but legislation has been more effective than these efforts. Examples include factory settings of hot-water heaters, fire-safe cigarettes, and flammability standards for children's bedclothes.

**CLINICAL PRESENTATION AND EVALUATION**

Despite a broad spectrum of burn injury severity, from a practical perspective, the number of burn-injured children can be divided into 2 categories: those reasonably managed in the outpatient setting and those requiring inpatient or burn center care. This decision is based on an evaluation of the child and of the wound.

**Evaluating the Burn Patient**

An evaluation of the child should precede an evaluation of the wound, especially if the burn is large or

physiologically threatening. Patient evaluation is organized into a primary and a secondary survey, following the guidelines of the American College of Surgeons Committee on Trauma and the Advanced Burn Life Support Course of the American Burn Association.

As in trauma, the primary survey begins with an assessment and control, if necessary, of the airway. Deep burns of the face and neck can result in progressive airway edema. Rarely, a child will aspirate hot liquids, resulting in very severe upper airway edema and mandating urgent intubation.

A burn-specific secondary survey evaluates issues uniquely associated with burn injury (Box 375-1). This process may take just a few seconds in a child with a small burn, but it can be much more time consuming if the injury is large. In children with small injuries, essentials include a detailed determination of the mechanism of injury, a screen for associated trauma, consideration of the possibility of abuse, and a detailed assessment of the burn wound. Delayed presentation for care, confusing and conflicting stories, sharply demarcated margins, immersion patterns, and contact injuries are physical findings worrisome for abuse or neglect. All such children should be admitted for evaluation (Figure 375-1).

### Evaluating the Burn Wound

After the patient has been evaluated, the burn wound should be examined for size, extent, depth, and circumferential components. Decisions regarding outpatient care, hospitalization, or transfer will generally be made based on this information.

Burn extent is best estimated using a chart based on the Lund-Browder diagram that compensates for the changes in body proportions with age (Figure 375-2). An alternative is a modified *rule of nines*, in which the head and neck area is given 18% (instead of the adult 9%), each lower extremity is given 15% (instead of the adult 18%), each upper extremity is given 10% (instead of the adult 9%), and the anterior and posterior torso are each given 16% (instead of the adult 18%). For scattered or irregular burns, the entire palmar surface of the patient's hand represents approximately 1% of the body surface over all ages.

Burn depth is classified as first, second, third, or fourth degree. First-degree burns are red, dry, and painful and are often deeper than they appear, sloughing the next day. Second-degree burns are red, wet, and very painful (Figure 375-3, A). Enormous variability exists in their depth, ability to heal, and propensity to hypertrophic scar formation. Third-degree burns are leathery, dry, insensate, and waxy (Figure 375-3, B). Fourth-degree burns involve underlying subcutaneous tissue, tendon, or bone (Figure 375-3, C).

Nearly or completely circumferential burns should be identified for special monitoring and possible escharotomy. If across the torso, such wounds will interfere with ventilation. When they involve an extremity, limb-threatening ischemia may occur during resuscitation. This complication usually becomes an issue 12 to 24 hours after injury. These procedures can be performed with coagulating electrocautery. They can be

frightening and painful, and anesthesia or sedation is generally required in children. The physician should avoid damaging uninjured skin or superficial neurovascular structures.

### Selection for Outpatient Versus Inpatient Care

Most burns can be successfully managed in the outpatient setting. However, poorly provided outpatient burn care can be frustrating and painful for patients and providers. The key is careful patient selection and a detailed care plan. Several issues should be considered when making this decision (Box 375-2).

## MANAGEMENT

### Outpatient Burns

Many correct answers exist to the question, "How should outpatient burn wounds be treated?" However, certain characteristics are universal. The wound should be kept clean and inspected regularly for infection. Accumulated exudate and topical medications should be periodically cleansed. The small superficial burns managed in the outpatient setting present a low risk for infection; therefore, clean rather than sterile technique is reasonable. If topical agents rather than membrane dressings are used, then wounds may be cleansed with lukewarm tap water and a bland soap. Soaking adherent dressings before removal will decrease the pain associated with daily wound care. The wound is gently cleansed with a gauze or clean washcloth, inspected for any sign of infection, patted dry with a clean towel, and redressed. Instructing the patient and family to return promptly if they notice erythema, swelling, increased tenderness, lymphangitis, odor, or drainage is important so that infectious complications can be addressed early. The frequency of wound cleansing and dressing change is debated, but most small burns are adequately managed with a daily cleansing and dressing change. In some cases, a membrane dressing, designed not to be changed daily, is applied when early surgery is clearly not needed and early infection has not occurred. Pain and anxiety can be an issue for many children. Some of these children benefit from an oral narcotic given 30 to 60 minutes before a planned dressing change. Especially if dressings are occlusive, pain in between dressing changes tends to be modest for most children.

Increasing pain and anxiety associated with dressing changes, inability to keep scheduled follow-up appointments, delayed healing, signs of infection, or a wound that seems deeper than appreciated at the time of the initial examination should prompt early return and specialty evaluation. Wounds selected for outpatient management are usually fairly superficial and heal within 2 weeks. Patients with mid and deep dermal injuries may have a more problematic component, with resulting scarring that may benefit from specialty evaluation. Finally, wounds of the face, ears, hands, genitals, and feet have a functional and cosmetic importance out of proportion to their wound size. In some cases, early specialty evaluation may be prudent because initial care can have an effect on long-term outcome.

**BOX 375-1 Burn-Specific Secondary Survey****HISTORY**

- Mechanism of injury.
- Closed space exposure and extrication time.
- Delay in seeking attention.
- Fluid and pain medication given during transport.
- Prior illnesses and allergies.
- Prior child protective services involvement.

**HEAD, EARS, EYES, NOSE, AND THROAT**

- Early examination of the globes for corneal burns.
- Tonometry for intraocular hypertension if deep facial burns.
- Check for intraocular hypertension if extreme periorbital swelling or very deep periorbital burns are noted. Patient may need lateral canthotomy orbital decompression.
- Progressive hoarseness, perioral and intraoral burns, and carbonaceous material may signify inhalation injury.
- Consider hot liquid aspiration.
- Continuously assess endotracheal tube security.

**NECK**

- Radiographic evaluation if indicated by injury mechanism.
- Rare need for neck escharotomy.

**CARDIAC SYSTEM**

- Cardiac monitoring after significant electrical injury.

**PULMONARY SYSTEM**

- Chest escharotomy indicated if near circumferential torso burn and difficulty with ventilation.
- Inhalation injury can be associated with airway obstruction and bronchospasm initially.

**VASCULAR SYSTEM**

- Perfusion of burned extremities should be closely monitored.
- Escharotomy is indicated for decreasing perfusion.
- Fasciotomy is indicated after electrical or deep thermal injury when flow is compromised.
- Compartment pressures can be followed in equivocal extremities.
- Worrisome extremities should be decompressed based on serial examination.

**ABDOMEN**

- Nasogastric tubes are often indicated, especially before air transport.
- Inappropriate volume requirement may be a sign of an occult intra-abdominal injury.
- Torso escharotomy may be required to facilitate ventilation.
- Ulcer prophylaxis is indicated in all patients with serious burns.

- Consider abdominal compartment syndrome in very large burns or delayed resuscitation.

**GENITOURINARY SYSTEM**

- Catheterization is appropriate in those who require a fluid resuscitation.
- Ensure that the foreskin is reduced over the bladder catheter.

**NEUROLOGIC SYSTEM**

- Level of consciousness is often reduced during the hours after injury.
- Computed tomographic scanning is useful to exclude head injury if mechanism appropriate.

**EXTREMITIES**

- Monitor perfusion if near circumferential burns or electrical injury is present.
- Limbs at risk for decreased perfusion should be dressed so that they can be easily reexamined.

**WOUNDS**

- Evaluate wounds for size, depth, and circumferential components.
- Wounds are often underestimated in depth and size initially.

**ELECTRICAL FACTORS**

- Consider monitoring cardiac rhythm for high (>1,000) or intermediate (>220) volt exposures.
- Neurologic and ocular examination is important.
- Extremities should be serially evaluated for intracompartmental edema.
- Bladder catheters are useful in high-voltage exposures to document clearing of pigment.

**CHEMICAL FACTORS**

- Irrigate wounds with tap water for at least 30 minutes.
- Irrigate eyes with isotonic crystalloid solution.
- Blepharospasm may require ocular anesthetic.
- Hydrofluoric acid may be complicated by life-threatening hypocalcemia.

**TAR**

- Cool with tap water irrigation and remove later with a lipophilic solvent.

**LABORATORY AND RADIOGRAPHY DATA**

- Evaluate blood gas when inhalation injury is present.
- Normal carboxyhemoglobin does not eliminate significant exposure.
- Baseline hemoglobin and electrolytes can be helpful later.
- Perform a urinalysis for occult blood in patients with deep thermal or electrical injuries.
- Perform radiographic evaluation as needed for mechanism of injury.

**Figure 375-1** Some burn patterns are worrisome for abuse or neglect. This photograph illustrates popliteal flexor sparing, which may indicate abuse or neglect.

Intervals between discharge and first clinic follow-up and between subsequent follow-up visits will vary depending on the depth and location of the burn, surgery needed, and competence and comfort of the home-care providers. In general, a first follow-up a week after initial discharge is reasonable, rapidly increasing the duration of time between visits to 6 months, depending on patient progress.

### Wound Medications and Membranes

The proliferation of wound medications and membranes is increasingly confusing. Thankfully, most superficial wounds heal well under any of these products. Wound medications and membranes provide 3 benefits: (1) pain control, (2) prevention of wound desiccation, and (3) reduction of wound colonization.

A wide variety of topical wound medications are available, ranging from aqueous solutions to antibiotic-containing ointments and debriding enzymes. Most topical agents in outpatient use have a viscous carrier that prevents wound desiccation and a more or less broad antibacterial spectrum that reduces wound colonization. A gauze wrap minimizes soiling of clothing and protects the wound from trauma. Superficial burns are commonly treated with a clear, viscous, antibacterial ointment containing low concentrations of various antibiotics. Wounds around the eyes can be treated with topical ophthalmic antibiotic ointments. Silver sulfadiazine is commonly used for deeper injuries because it is painless on application and has a broad spectrum of antibacterial activity. Significant ear burns should be treated with mafenide acetate because it is the only agent that will penetrate the relatively avascular cartilage.

Wound membranes play an increasing role in outpatient burn programs. They provide transient physiologic wound closure while the underlying wound heals (Box 375-3). Physiologic closure implies a degree of protection from mechanical trauma, vapor transmission characteristics similar to skin, and a physical barrier to bacteria. The major benefit of wound membranes is that when successful, they minimize wound

manipulations. These membranes help create a moist wound environment with a low bacterial density and are generally intended for use on selected clean superficial wounds and donor sites. Occlusive synthetic membranes must be used with caution if wounds are not completely clean and superficial because submembrane infection can occur, deepening underlying wounds and causing systemic infection and toxicity. Membrane dressings are generally applied over a clean wound, without intervening topical medications. When used, these products are often applied after a period of care with a topical medication that allows the wound to be inspected and a clear determination made that the wound is superficial and will likely heal.

### Inpatient Burns

Inpatient burn care is resource intensive. A system of burn center verification has evolved to ensure that children requiring such care receive coordinated efforts by experienced providers. An increasing body of data supports the efficacy of this approach. Transfer to a burn center should be considered for patients meeting American Burn Association referral criteria (Box 375-4). Care of severe burns can be divided into 4 phases: initial evaluation and resuscitation; initial excision and biologic closure; definitive wound closure; and rehabilitation and reconstruction. Significant critical care needs often exist during the first 3 phases of care.

Priorities during the initial evaluation and resuscitation phase are to document the entire extent of the injury, including nonburn trauma, and to address the physiologic changes that accompany burns. This phase occupies the first 24 to 72 hours after injury. These needs will vary with the mechanism of injury, extent of burn, and child's social and medical history. If burns involve more than approximately 15% of the body surface, then a poorly understood syndrome of reduced capillary integrity is seen, necessitating a fluid resuscitation. This complication typically abates after about 24 hours. Any one of several burn formulas may be used to initiate resuscitation, but all should be carefully titrated to individual patient needs. One commonly cited formula is listed in Box 375-5.

In the initial excision and biologic closure phase, large full-thickness injuries are identified and excised, ideally within the first few days of injury, to avoid otherwise inevitable local and systemic sepsis, and systemic inflammation. Resulting wounds are closed with autograft or, in some circumstances, temporary wound membranes. This strategy changes the natural history of the injury from inevitable sepsis and inflammation to a more controlled wound closure situation.

In the definitive wound closure phase, which varies in duration with wound size and complexity, temporary wound membranes are replaced with autologous tissue, and small complex wounds, such as those on the hands and face, are addressed. In very large burns, this process may take many weeks. Intensive care is often a prominent part of the first 3 phases of care. Verified burn programs have embedded critical care units. Proper attention to pain and anxiety management is essential in all phases of care.

Burn Estimate: Age Versus Area

	Birth– 1 yr	1–4 yr	5–9 yr	10–14 yr	15 yr	2°	3°	Total
Head	19	17	13	11	9			
Neck	2	2	2	2	2			
Anterior trunk	13	13	13	13	13			
Posterior trunk	13	13	13	13	13			
Right buttock	2½	2½	2½	2½	2½			
Left buttock	2½	2½	2½	2½	2½			
Genitalia	1	1	1	1	1			
Right upper arm	4	4	4	4	4			
Left upper arm	4	4	4	4	4			
Right lower arm	3	3	3	3	3			
Left lower arm	3	3	3	3	3			
Right hand	2½	2½	2½	2½	2½			
Left hand	2½	2½	2½	2½	2½			
Right thigh	5½	6½	8	8½	9			
Left thigh	5½	6½	8	8½	9			
Right Leg	5	5	5½	6	6½			
Left Leg	5	5	5½	6	6½			
Right foot	3½	3½	3½	3½	3½			
Left foot	3½	3½	3½	3½	3½			
					<b>Total</b>			

**Figure 375-2** Burn chart for estimating the extent of injury. Numbers equal the percentage of total body surface.

**Figure 375-3** A, Second-degree burns are red, wet, and very painful. Enormous variability exists in their depth, ability to heal, and propensity to hypertrophic scar formation. B, Third-degree burns are leathery, dry, insensate, and waxy. This wound demonstrates peripheral second-degree component with central third-degree areas. C, Fourth-degree burns involve underlying subcutaneous tissue, tendon, or bone.

**BOX 375-2 Requirements for Outpatient Burn Management**

- Clear airway—has no need for airway monitoring.
- Wound size should be generally less than 10% (fluid resuscitation not needed).
- Child must be able to take in adequate fluid by mouth.
- No significant burns occur to the face, ears, hands, genitals, or feet.
- Family must have the resources to support an outpatient care plan.
- Adult caregiver should be able to stay at home with the child.
- Adult who is able to perform wound cleansing, inspection, and dressing changes should be available.
- Child must have transportation and access to clinic follow-up.
- Family must have transportation for clinic and emergency visits.
- No suspicion of abuse or neglect is noted.
- No clearly full-thickness areas that will require surgery are found.

**BOX 375-3 Partial Listing of Some Commonly Used Wound Membranes—Selected Characteristics**

- Porcine Xenograft (Brennan Medical, St Paul, MN): adheres to coagulum, excellent pain control
- Biobrane (Dow-Hickham, Sugar Land, TX): bilaminate, fibrovascular in growth into inner layer
- Acticoat (Westhaim Biomedical, Saskatchewan, Canada): nonadherent dressing that delivers silver
- Aquacel-Ag (Convatec, Princeton, NJ): absorptive hydrofiber that delivers silver
- Mepilex Ag (Mölnlycke Health Care, Gothenburg, Sweden): absorptive silver-releasing dressing
- Various semipermeable membranes: provide vapor and bacterial barrier
- Various hydrocolloid dressings: provide vapor and bacterial barrier; absorb exudate
- Various impregnated gauzes: provide barrier while allowing drainage

**BOX 375-4 American Burn Association Burn Center Referral Criteria**

- Second- and third-degree burns over more than 10% of total body surface area (TBSA) in patients younger than 10 years or older than 50 years
- Second- and third-degree burns over more than 20% of TBSA in patients aged 10 to 50 years
- Second- and third-degree burns that involve the face, hands, feet, genitalia, perineum, and major joints
- Third-degree burns over more than 5% of TBSA in any age group
- Electrical burns, including lightning injury
- Chemical burns
- Inhalation injury
- Burn injury in patients with preexisting medical disorders that might complicate management, prolong recovery, or affect mortality
- Any patients with burns and concomitant trauma (eg, fractures) in which the burn injury poses the greatest risk of morbidity or mortality. (In such cases, if the trauma poses the greater immediate risk, then the patient may be treated initially in a trauma center until stable before being transferred to a burn center. Physician judgment will be necessary and should be in concert with the regional medical control plan and triage protocols.)
- Hospitals without qualified personnel or equipment for the care of children should transfer patients with burns to a burn center with these capabilities
- Burn injury in patients who will require special social or emotional or long-term rehabilitative support, including cases involving suspected child abuse or substance abuse

Adapted with permission from American Burn Association. *Advanced Burn Life Support Course: Provider Manual*. Chicago, IL: American Burn Association; 2011: 25-26.

The final phase of care, rehabilitation and reconstruction, is of the longest duration. This phase begins as soon as the child is able to participate and lasts well past discharge, again depending on wound size and complexity. This process requires initially ranging and splinting and progresses through strength and endurance training. Long-term scar management and emotional support must be a part of this plan. As children

grow and scars contract, burn reconstruction procedures become important. A long-term follow-up plan is an essential part of discharge.

**Complications**

In the outpatient setting, patient selection should ensure that major complications are few. The most common issues that arise are wound sepsis, excessive pain

**BOX 375-5 Consensus Resuscitation Formula****FIRST 24 HOURS****Adults and Children Weighing More Than 20 kg**

- Lactated Ringer solution: 2–4 mL/kg per percentage of total body surface area (TBSA) burned per 24 hours (first half in first 8 hours)
- Colloid: In many children, particularly those with small injuries, no colloid is advised in the first 24 hours. However, colloid, generally as 5% albumin solution, is increasingly used early in resuscitation of patients with large burn injuries. This is program specific and should ideally be discussed with the unit to whom the child with a large injury will be referred. The author routinely replaces a maintenance rate of lactated Ringer solution with a similar volume of 5% albumin solution in children with burns over 30% BSA during the first 24 hours of resuscitation.

**Children Weighing Less Than 20 kg**

- Lactated Ringer solution: 2–3 mL/kg per percentage of TBSA burned per 24 hours (first half in first 8 hours)
- Lactated Ringer solution with 5% dextrose: Maintenance rate (approximately 4 mL/kg/hr for the first 10 kg, 2 mL/kg/hr for the next 10 kg, and 1 mL/kg/hr for weight over 20 kg)
- Colloid: In most circumstances, none; however, many physicians initiate colloid infusions in children with large burns. The author routinely replaces a maintenance rate of lactated Ringer solution with a similar volume of 5% albumin solution in children with burns over 30% BSA during the first 24 hours of resuscitation.

**SECOND 24 HOURS—ALL PATIENTS**

- Crystalloid: To maintain urine output. If silver nitrate is used, then sodium leeching will mandate continued isotonic crystalloid. If other topical is used, then free-water requirement is significant. Serum sodium should be monitored closely. Nutritional support should begin, ideally by the enteral route.
- Colloid (5% albumin in Ringer's lactate solution):
  - 0%–30% burn: none
  - 30%–50% burn: 0.3 mL/kg per percentage of TBSA burned per 24 hours
  - 50%–70% burn: 0.4 mL/kg per percentage of TBSA burned per 24 hours
  - 70%–100% burn: 0.5 mL/kg per percentage of TBSA burned per 24 hours
  - Colloid, generally as 5% albumin solution, is increasingly used early in resuscitation of children with large burn injuries.

and anxiety, and underestimation of burn depth. The most common wound infection in this setting is streptococcal cellulitis, which initially produces surrounding erythema that progresses to lymphangitis and systemic toxicity (Figure 375-4). Children with cellulitis often need admission for antibiotics, observation, and, sometimes, surgery. In some situations, adequate pain and anxiety management is difficult in the outpatient setting, especially around dressing changes. This problem can be addressed with judicious medication and, in some instances, carefully monitored membrane dressings. Some children will require admission for pain management. For burn depth to be underestimated initially is common, with areas of full-thickness injury not appreciated for several days. These children may require admission for surgery.

As burn severity increases, the local injury is accompanied by an increasing degree of systemic derangement. An initial phase of reduced perfusion and metabolic rate, which lasts 24 to 48 hours, is followed by a phase of protein catabolism and a hyperdynamic circulation, lasting until well after wound closure. Management of this physiologic process is an essential part of inpatient burn care. Children with large burns are susceptible to a host of other complications related to sepsis and organ failures. Careful monitoring and early intervention are essential to successful outcomes.

**Figure 375-4** The most common infectious complication in the outpatient setting is streptococcal cellulitis, as demonstrated here. Note blanching by examiner's fingers, suggesting surrounding erythema.

**LONG-TERM CARE**

Burn wounds and grafts typically develop some degree of hypertrophy. This process involves a gradual increase in vascularity and collagen deposition in the

months after healing. Some wounds will demonstrate significant contracture formation, with important functional and aesthetic consequences. Many children will have bothersome pruritus. A long-term follow-up plan consisting of scar management strategies, rehabilitation, reconstructive surgery, and emotional support will facilitate optimal outcomes. This care is best provided in a multidisciplinary burn clinic, ideally part of a comprehensive burn program. With such supports in place, the long-term outcome for children is surprisingly good. When managed in a comprehensive follow-up program, even patients who have suffered devastating burns may become happy and productive adults.

### PEDIATRIC CARDIOPULMONARY RESUSCITATION

Élise W. van der Jagt, MD, MPH

#### HISTORY

An estimated 23,440 infants younger than 1 year old and 18,888 children between 1 and 19 years old died in the United States during 2012 from various causes. The mortality rate is clearly biphasic, with most deaths occurring in the first year of life and then again in the 15- to 19-year age group. Deaths of infants younger than 1 year are the result primarily of congenital malformations (20%) and conditions relating to prematurity and very low birth weight (18%). However, 7% of deaths are the result of sudden infant death syndrome, and 5% are caused by unintentional injuries. In children older than 1 year, injuries are the leading cause of death.

Although children also die from acute cardiac disease, including dysrhythmias and congenital heart disease, the major causes of death are substantially different from the causes of adult cardiac arrest, in which acute myocardial ischemia secondary to coronary artery disease is the predominant cause. Such myocardial ischemia often results in an acute dysrhythmia, usually ventricular fibrillation or ventricular tachycardia, and cardiac arrest. Unless children suffer a traumatic death, reasons for cardiopulmonary arrest are more commonly related to respiratory failure, infection, shock, and metabolic and neurologic events. Nevertheless, up to 17% of children with out-of-hospital cardiac arrest have ventricular fibrillation, similar to the 5% recently described for pediatric in-hospital arrests. Thus, many of the efforts in improving outcome for adults with cardiac arrest are also applicable to pediatric patients.

Outcomes from pediatric cardiopulmonary arrest are generally poor. Survival to hospital discharge from out-of-hospital arrest is less than 10%, with even fewer having intact neurologic function. Children who have sustained a cardiac arrest from a submersion injury have somewhat better outcomes, at 23% survival to hospital discharge and 6% with intact neurologic survival. However, based on the most recent data from the American Heart Association (AHA) “Get With the Guidelines: Resuscitation” (formerly called the National Registry of Cardiopulmonary Resuscitation), a registry of adult and pediatric in-hospital arrests, overall risk-adjusted survival in pediatric patients is 43%, a threefold increase in survival between 2000 and 2009. Asystole/pulseless electrical activity is the most common initial cardiac arrest rhythm (85%). Based on several studies, the outcomes

of pediatric respiratory arrest alone are better, with a survival of 75%; however, a 25% mortality rate is still highly significant.

Given that the outcomes of respiratory and cardiac arrest are poor, a proactive approach is best:

1. Identify children who are at risk for respiratory and cardiac arrest.
2. Institute treatments that prevent deterioration of the at-risk child.
3. If respiratory or cardiac arrest occurs, treat the child expeditiously and effectively using evidence-based therapies.

Until the mid-1980s, training was focused primarily on the third step of this approach, the treatment of pediatric patients who were in cardiac arrest. Currently the preventive approach outlined in steps 1 and 2 is also recognized as having significant importance. Moreover, the AHA has emphasized the importance of a community and serial approach to the significant problem of cardiopulmonary arrests by advocating for a concept called the Chain of Survival. Each link is integrally related to the next, and only if all the links are accomplished will it be less likely that death and disability will occur from cardiac arrest. Because the major causes of pediatric cardiopulmonary arrest are not cardiac in origin, but are from injuries, sudden infant death syndrome, respiratory failure, sepsis, neurologic diseases, and other illnesses, a separate Pediatric Chain of Survival has been developed for the management of pediatric critical illness and injury. It consists of prevention; early cardiopulmonary resuscitation (CPR); prompt access to the emergency response system; rapid pediatric advanced life support; and integrated post-cardiac arrest care.

#### ASSESSMENT

Given the paramount importance of recognizing children who are critically ill or injured before they deteriorate into respiratory or cardiac arrest, a rapid systematic assessment is required, with due attention paid to possible respiratory and circulatory compromise. This process requires a rapid performance of those parts of the physical examination that pertain especially to the respiratory, circulatory (including cardiac and vascular systems), and neurologic systems. The neurologic system is especially important in that failures of either or both respiratory and circulatory systems will have an effect on neurologic function. The AHA and the American Academy of Pediatrics (AAP) have jointly developed an excellent systematic approach, which is included in their Pediatric Advanced Life Support Course training materials, accessible via the AHA Web site ([www.heart.org](http://www.heart.org)).

The components of this rapid, systematic evaluation include an initial impression, a primary assessment using an A-B-C-D-E approach to rule out immediate, life-threatening problems, a secondary assessment

that includes both a history and a more detailed head-to-toe physical examination, and a tertiary assessment using bedside monitoring and laboratory and radiologic diagnostic tests (Table A-1).

### Initial Impression

The *initial impression* is a quick look at the child, focusing on level of consciousness, general appearance, work of breathing (including its absence or only gasping, abnormal airway sounds, and retractions), and color (may be altered by either or both respiratory and circulatory problems). A quick decision is made on whether this child might be in respiratory failure, circulatory failure, or both, including full cardiopulmonary arrest, and immediate management is begun, such as calling for help, immediate provision of CPR if

necessary (after a pulse check), providing oxygen, and obtaining a monitor.

### Primary Assessment

The child is examined in a systematic fashion using an **A** (airway), **B** (breathing), **C** (circulation), **D** (disability), and **E** (exposure) approach.

**A: Airway**—the examiner quickly determines whether the airway is patent with air able to flow into and out of the chest, whether it is maintainable with minimal head or jaw positioning or with an insertion of an oropharyngeal or nasopharyngeal airway, or whether the child needs establishment of a laryngeal mask airway (LMA), invasive airway, such as an endotracheal tube (ET) or cricothyroidotomy.

**B: Breathing**—respiratory rate, work of breathing, and lung sounds are determined by visual inspection and auscultation of the chest at the apices and in the peripheral lung fields (lung bases posteriorly and in axillae). The purpose is to determine the presence of life-threatening problems such as apnea, respiratory failure with inadequate oxygenation and ventilation, pneumothorax, hemothorax, severe wheezing, or rales from congestive heart failure or pneumonia. Normal respiratory rates are shown in Table A-2.

**C: Circulation**—heart rate, blood pressure (BP), peripheral and proximal pulses, capillary refill, distal extremity temperature, and distal extremity color should all be noted.

Changes in heart rate reflect changes in cardiac output the most quickly, but unfortunately these changes are nonspecific. Children have a wide range of normal heart rates, and rates are highly dependent on activity (see Table A-1). For neonates, the typical sleeping heart rate should be no greater than 160 beats per minute (bpm). By age 2 years, heart rates are usually between 75 and 160 bpm, with a mean of approximately 130 bpm; from 2 to 10 years of age, the sleeping heart rate should be no greater than approximately 90 bpm; and over age 10, even the non-sleeping heart rate should be no more than 100 bpm. Heart rates above a certain level are highly associated with a primary cardiac dysrhythmia. Heart rates that are above 220 bpm for infants, 180 bpm

12–14 yr	1.07–1.22	38–48	50–100	90	12–20
15–16 yr	1.30–1.60	53–58	50–100	90	12–18
Adult	1.40–1.70	60–70	50–100	90	12–18

<sup>a</sup>Pulse rate range includes sound sleep and vigorous crying.

<sup>b</sup>Systolic blood pressure less than fifth percentile.

<sup>c</sup>Respiratory rate above 60 or below 10 respirations/minute is abnormal at any age.

for children up to age 8, and over 160 bpm for older children are suggestive of a primary dysrhythmia such as supraventricular or ventricular tachycardia. Sinus tachycardia from volume depletion is typically at a lower rate. When a sinus tachycardia fails to compensate adequately for tissue oxygen needs, eventually hypoxia, acidosis, and ultimately bradycardia develop. Bradycardia is present when the heart rate is below 60 bpm and, in a distressed child, is always a sign of impending cardiac arrest.

Blood pressure is the product of cardiac output multiplied by the peripheral vascular resistance. It should be measured early to detect decompensated hypotensive shock. Hypotension is a late and serious finding in patients who are in shock. A useful way to remember the minimally acceptable systolic BP is

- If younger than 1 month of age, systolic BP above 60 mm Hg
- From 1 month to 1 year, systolic BP above 70 mm Hg
- From 1 to 10 years, systolic BP above  $70 + (2 \times \text{the age in years})$  mm Hg
- Older than 10 years, systolic BP above 90 mm Hg

These parameters have been derived from the lowest fifth percentile of office BPs in normal children taken from cross-sectional data sets. An infant or child whose BP is below these parameters should be considered hypotensive.

Palpating the peripheral pulses (a reflection of peripheral perfusion) allows the examiner to estimate the stroke volume, heart rate, and, indirectly, the cardiac output. The stroke volume is the volume of blood pumped out of the heart with each heartbeat. The cardiac output is the volume of blood pumped by the heart every minute (heart rate multiplied by stroke volume). Organ perfusion is determined by the cardiac output and the peripheral vascular resistance. Peripheral pulses that can be palpated are the radial, brachial, dorsalis pedis, and posterior tibial arteries. Central pulses are the carotid, axillary, and femoral pulses. Attention should be given to the quality of the pulse, especially whether it is bounding (consistent with low systemic vascular resistance) or narrow/thin (narrow pulse pressure and a high systemic vascular resistance). Decreased distal pulses are consistent with circulatory compromise.

When circulatory compromise occurs, the skin loses its perfusion first, because blood is shunted to more important organ systems. Skin perfusion is assessed by determining capillary refill time (ie, the time required for normal skin color to return after blanching pressure is applied); this interval should be 2 seconds or less (or less than the time required to say “capillary refill”). When testing for capillary refill, the extremity used should be kept at the level of the heart. Poor perfusion also can be identified by mottled skin color, especially distally (acrocyanosis), and cool hands and feet, with an often noticeable line of demarcation between warm skin proximally and cool skin distally.

Once these circulatory physical parameters have been assessed, a determination can be made as to whether the patient either has no circulatory compromise, is in early compensated shock (normotensive circulatory failure), or is in late decompensated shock (hypotensive circulatory failure).

**D: Disability**—a quick neurologic examination is performed by evaluating the level of consciousness (AVPU: Alert, responds to Voice, responds to Pain, Unresponsive), pupillary response to light, motor response to discomfort, and muscle tone. Both respiratory and circulatory failure can result in blunting of mental status because of hypoxia or poor oxygen delivery. However, a primary neurologic problem should also be excluded, particularly given that many critically ill children have sustained a head injury, have seizures, or have an infectious neurologic disease such as meningitis.

**E: Exposure**—attention must be given to the core temperature of the child because both elevated and low temperatures may alter other physiologic parameters. In addition, a thorough inspection of the child's skin is necessary to ensure that areas of bleeding, rashes, and signs of trauma are not missed.

No more than about 60 seconds is needed to perform the primary assessment and determine whether the child is stable, has respiratory distress only, has respiratory failure, has compensated or decompensated shock, or has combined cardiopulmonary failure. This last physiologic state is usually present when a child exhibits agonal breathing, cyanosis, and bradycardia. Usually this state will have been identified already during the general assessment described previously.

The necessity for instituting urgent treatment is dictated by the results of the initial impression and primary assessment. Monitoring should be initiated with at least a continuous pulse oximeter and frequent BP checks, but often there is benefit from continuous electrocardiographic (ECG) monitoring as well. A high concentration of oxygen (non-rebreather will give approximately 90% to 100% fraction of inspired oxygen [ $\text{Fio}_2$ ]) should be provided to all children with respiratory and circulatory problems. If significant respiratory distress is present, the child may be in respiratory failure, and assisted ventilation with a bag-mask device should be provided with progression toward ET intubation as needed. Any form of shock that is related to volume depletion, whether because of extrinsic losses of water, loss of blood, or a redistribution of intravascular volume such as that seen in septic or anaphylactic shock should be treated with intravenous (IV) (or intraosseous [IO] if necessary) administration of 20 mL/kg of normal saline or Ringer's lactate given within approximately 5 to 10 minutes (often requiring a 3-way stopcock and syringe to draw rapidly from a bag of fluid and manually push it into the patient's IV or IO line). The need for further boluses is determined by response in heart rate (tachycardia would be expected to decrease) and restoration of normal vital signs. Dysrhythmias should be treated with antiarrhythmic maneuvers (eg, facial ice for supraventricular tachycardia [SVT]) or medications, as described later and in the dysrhythmia algorithms.

### Secondary Assessment

The secondary assessment consists of performing a focused history and a complete physical examination.

A focused history can be remembered with the mnemonic **SAMPLE**:

- Signs and symptoms
- Allergies

**Medications****Past history****Last meal****Events**

Although all of the items in the SAMPLE mnemonic are important, special attention should be given to the last time food or drink was ingested. If the child requires assisted ventilation by bag or needs to have an ET tube inserted, emesis of stomach contents may occur, especially if the time interval from the last meal is short (<6 hours). Use of a Sellick maneuver (anterior cricoid pressure directed posteriorly during bagging or intubation) may decrease the likelihood of emesis by occluding the esophagus and decreasing the chance of introducing air/oxygen into the stomach. It should only be attempted in an unconscious patient, and, in small children, anterior cricoid pressure may occlude the compliant trachea. The physician should ensure the immediate availability of large-bore suction (pediatric and adult size Yankauer suction) to remove vomitus or secretions and to prevent aspiration.

The past history is important because it may reveal medical problems that are related to the current condition of the child or that should be taken into consideration when management is instituted.

A focused head-to-toe standard physical examination will provide a more fine-tuned constellation of clinical clues to the physiologic state of the child. In this examination, important areas to include are the head, the fontanelles in infants (flat or sunken vs full or bulging), ears, eyes (especially pupillary reaction), nose, mouth, teeth and pharynx, neck (supple or stiff), more detailed lung and heart sounds, abdominal examination (especially assessing for tenderness), organomegaly (such as an increase in liver or spleen size), bowel sounds and distention, extremities (evidence of injury), color change, skin (evidence of bleeding and rashes), and neurologic examination assessing for mental status, movement, deep-tendon reflexes, cranial nerves, and muscle tone.

**Tertiary Assessment**

The tertiary assessment is performed by using non-historical or direct physical examination techniques. This assessment includes diagnostic modalities such as pulse oximetry and capnography, bedside tests such as finger-stick blood glucose, laboratory and imaging tests, and invasive monitoring. Some of these tests might be performed simultaneously with the earlier parts of the assessment. Once the rapid preliminary clinical assessment has been performed to determine the most likely physiologic state of the child, appropriate laboratory tests should be ordered to define further the child's physiologic state and treatments necessary, and to assist in determining etiology. In a critically ill child, the important tests that should be considered include an arterial blood gas level; a chest radiograph; electrolyte (sodium, potassium, chloride, bicarbonate, calcium, magnesium) levels; blood urea nitrogen levels; glucose level; lactate level; a complete blood count (hematocrit, white blood cells with differential, platelets); a urine analysis; and cultures of blood, urine, and spinal fluid as appropriate.

Although the time needed to obtain these results can be lengthy, the information obtained will be useful in determining the severity of the illness and the further management required. Meanwhile, ongoing advanced life support should be given as indicated by the clinical examination and revised as laboratory and radiologic tests return.

**DIAGNOSIS OF PHYSIOLOGIC STATE****Respiratory Distress, Failure, or Arrest**

The principal functions of the respiratory system are to introduce oxygen into the blood and to remove carbon dioxide. Failure of the respiratory system results in significant compromise to cellular metabolism, changing aerobic to anaerobic metabolism with the accumulation of lactic acid, and an increase in carbon dioxide, resulting in a respiratory acidosis. The initial physiologic responses to failure of oxygenation and ventilation are usually an increase in respiratory rate with efforts to improve air entry, and an increase in heart rate to improve oxygen delivery to the tissues. However, in young children these responses may be blunted, and bradycardia from hypoxia is common. The presence of central (oral or perioral) pallor and cyanosis is an indicator of significant hypoxemia and should be treated rapidly with administration of 90% to 100% oxygen via a non-rebreather mask with oxygen reservoir while the remainder of the respiratory examination is completed. Bradypnea (slow respiratory rate) can indicate fatigue and failure of the brainstem to respond to normal stimuli for breathing; tachypnea can suggest either a need to maintain minute ventilation because of a smaller tidal volume (minute ventilation = tidal volume  $\times$  rate/minute) or because of an increase in metabolic rate and carbon dioxide production. Any respiratory rate over 60 breaths per minute or under 10 breaths per minute is abnormal at any age and might suggest respiratory distress, respiratory failure, or both. If respiratory compromise is untreated, it may rapidly and unexpectedly progress to respiratory failure and respiratory arrest.

*Respiratory distress* is defined as an increase in the work of breathing, typically characterized by an increase in the use of the main muscles used for breathing, as well as the use of muscles that typically do not contribute much to breathing (accessory muscles). Thus, the examiner might see retractions (intercostal, subcostal, sternal, substernal, sternocleidomastoid) and nasal flaring and head bobbing, hear a grunting sound on exhalation (to increase pressure in the airways to keep alveoli open), and notice an accentuation of abdominal breathing for children who have weak intercostal muscles.

Sounds heard during inhalation and exhalation may give an excellent clue to the etiology of the respiratory abnormalities. Stertor suggests nasopharyngeal obstruction; stridor suggests upper airway obstruction (usually in epiglottic/glottic and tracheal areas); wheezing suggests obstruction in the middle airways (eg, asthma, bronchiolitis); and inspiratory rales suggest lung parenchymal disease or alveolar fluid from pulmonary edema or congestive heart failure.

Asymmetric or diminished lung sounds might reflect the presence of atelectasis, pneumonia, a pleural effusion, or a pneumothorax.

*Respiratory failure* is defined as inadequate oxygenation, inadequate ventilation, or both. Although failure to oxygenate is now easily diagnosed by pulse oximetry, the diagnosis of respiratory failure still may be difficult to make purely on clinical grounds. Nasal capnography is a more recent advance that may be helpful in assessing the adequacy of ventilation even in the presence of adequate oxygenation. Generally, the greater the respiratory distress, the greater the likelihood of impending or existing respiratory failure. An arterial blood gas assessment will provide objective information about the adequacy of oxygenation and ability to remove carbon dioxide. A normal arterial pressure of oxygen ( $\text{Po}_2$ ) is usually 90 to 100 mm Hg (unless the child has congenital heart disease and part of the blood remains deoxygenated because it bypasses the lung as a result of intracardiac or extracardiac shunting, usually resulting in  $\text{Po}_2$  levels in the 35 to 45 range (oxygen saturation levels of 65% to 80%); a normal arterial pressure of carbon dioxide ( $\text{PCO}_2$ ) is between 38 and 42 mm Hg, and a normal pH is between 7.38 and 7.42. The  $\text{PCO}_2$  and pH are related such that a change in  $\text{PCO}_2$  of 10 mm Hg usually results in a pH change of 0.08. If the pH is normal in the presence of an elevated  $\text{PCO}_2$ , chronic rather than acute respiratory failure may be present because there has been time for the kidneys to absorb bicarbonate as a metabolic compensation.

If respiratory failure is present and no improvement is seen with oxygen administration or head positioning for optimal air entry, the examiner should initiate assisted ventilation with a bag-mask device and proceed with ET intubation.

*Respiratory arrest* is the cessation of any breathing efforts, with complete failure of ventilation and oxygenation. Failure of tissue oxygenation because of desaturated hemoglobin leads to anaerobic metabolism and a metabolic acidosis. Failure of carbon dioxide removal caused by a lack of air exchange results in an accumulation of carbon dioxide and respiratory acidosis. This combination of severe hypoxia and respiratory acidosis can lead rapidly to cardiopulmonary failure and cardiac arrest, sometimes called *asphyxial arrest*. Frequent brief apneic episodes, especially in infants, can be a harbinger of full respiratory arrest. Agonal respirations also suggest respiratory arrest and are not normal efforts at respiration; they are also known to occur in the presence of cardiac arrest, including ventricular fibrillation.

### Circulatory Failure or Compromise (Shock)

Circulatory failure or shock is a clinical state characterized by failure of the cardiovascular system to perfuse vital organs adequately, resulting in inadequate oxygen and substrate delivery to meet the metabolic needs of the tissues and inadequate removal of waste metabolites. This state results in anaerobic metabolism and accumulation of acids. In shock, the blood contains an adequate amount of oxygen, but it is

delivered poorly. In respiratory failure, the blood is delivered adequately to the body tissues, but the blood delivered is deficient in oxygen. Both conditions can lead to tissue hypoxia, anaerobic metabolism, acidosis, and cardiopulmonary arrest.

Shock (inadequate perfusion) may occur with a normal, increased, or decreased cardiac output and BP. In compensated shock, the cardiac output may be high or low, but the BP is normal. In decompensated or hypotensive shock, the BP is low and the child is at imminent risk of deteriorating into full cardiac arrest.

Shock may be classified by cause as hypovolemic, cardiogenic, distributive, or obstructive. Hypovolemic and distributive shock are the most common types of shock in children and are characterized by an inadequate preload in the ventricles and thus an inadequate stroke volume. Because preload is determined primarily by the volume of blood in the ventricle, any condition that decreases this amount will result in decreased output. Dehydration, blood loss, dilation of the peripheral vasculature with peripheral pooling or redistribution of blood volume, and increased permeability of capillaries with water lost may all result in a diminished amount of blood reaching the heart and thus a diminished preload. Cardiogenic shock results from an intrinsic inability of the heart to pump out an adequate amount of blood, even when the amount of preload is sufficient. Examples are myocarditis, cardiomyopathies, rhythm disturbances that interfere with cardiac output, and a heart that has been compromised during cardiac arrest or cardiopulmonary bypass. Obstructive shock is caused by failure of blood to enter or exit the heart because of some sort of obstruction. Examples are cardiac tamponade (the atria are collapsed because of impingement by fluid in the pericardial sac), tension pneumothorax (obstruction of venous return to the heart), obstructed valves such as critical aortic stenosis, or massive pulmonary embolus.

As described previously, to determine the presence and severity of compromise or shock, the examiner should thoroughly evaluate the heart rate, BP, peripheral and central pulses, and skin perfusion (capillary refill and distal extremity color and temperature). In addition, the level of consciousness and ongoing urinary output can be helpful in determining the severity of circulatory failure.

Any time a lack of sufficient oxygen delivery to the brain exists, abnormal central nervous system examination findings may occur. Because oxygen delivery depends on the amount of oxygenated hemoglobin in the blood and the cardiac output, failure of cardiac output will diminish the amount of oxygen delivered. Irritability, agitation, clouding of sensorium, and eventually lack of responsiveness are all clinical symptoms consistent with poor perfusion of the brain with concomitant poor oxygen delivery.

Similarly, the failure of normal urine production may be secondary to inadequate perfusion of the kidneys. The normal urinary output is 1 to 2 mL/kg/hr and depends on normal blood flow to the kidneys. Although this measure is unavailable during the initial evaluation, ongoing assessment of the volume of urine

produced over time is a valuable indicator of the adequacy of kidney perfusion.

### Cardiopulmonary Failure or Cardiac Arrest

Cardiopulmonary failure is a failure of both the respiratory and circulatory systems. Progression of cardiopulmonary failure leads to agonal or gasping respirations, bradycardia, cyanosis, and ultimately cardiac arrest. A patient in cardiac arrest is entirely unresponsive, does not move, and does not make sounds, although agonal gasps may be present (not to be confused with respiratory effort). Most pediatric patients who develop cardiac arrest usually progress to it via cardiopulmonary failure and lack of oxygen delivery. Such arrests are called *asphyxial arrests*. However, up to 19% of out-of-hospital pediatric cardiac arrests occur suddenly from a cardiac arrhythmia, such as ventricular fibrillation. These episodes are primary cardiac arrests. In both types of arrests, the heart can no longer eject an adequate amount of blood either to the lungs for oxygenation or to the systemic circulation for distribution of oxygen and other nutrients. If no intervention occurs within 5 to 10 minutes, the child will either die or survive with serious neurologic and other sequelae.

## RESUSCITATION MANAGEMENT

### General Overview

A considerable amount of resuscitation research from the last 20 years has demonstrated that the more quickly a person in cardiopulmonary arrest is provided with basic CPR and defibrillation when indicated, the better the outcomes are. For this reason, the AHA recommends immediate bystander CPR and the use of an electrical device for defibrillation (when indicated) within 3 to 5 minutes of the cardiac arrest. Although this information is taken primarily from adult studies, if children are given the same speed and type of treatment, they will likely have similar outcomes. Moreover, the most recent resuscitation science demonstrates that immediate and proper BLS, particularly chest compressions at an appropriate rate and depth, without interruption and allowing for adequate chest recoil, is foundational to all CPR. Furthermore, resuscitation science of the last 5 to 10 years now supports the concept that chest compressions should be done first, before initiation of ventilation. Studies on bystander-initiated hands-only CPR in adults with out-of-hospital witnessed arrests have shown that the addition of ventilations does not improve survival and may also discourage bystander CPR. Although ventilation remains an essential part of pediatric CPR and improving survival, there has been international consensus since 2010 that instead of CPR being *initiated* with airway opening, ventilation, and then circulation/compressions (A-B-C approach), it should be initiated with immediate chest compressions after a pulse check for no longer than 10 seconds, followed by airway opening and administration of ventilations (C-A-B approach). Effectively, this delays the onset of ventilations only minimally (<18 seconds) and allows for rapid onset of cardiac compressions.

Given the critical importance of basic life support in improving survival from cardiac arrest, this appendix will emphasize BLS, providing the pediatrician with some familiarity with this important skill. Nevertheless, because this knowledge is insufficient to enable the physician to perform this psychomotor skill, all professionals who provide care to pediatric patients should undergo formal training in basic CPR (BLS) and refresh these skills at least every 2 years and preferably more frequently.

Added to the need for this basic CPR training is the need to be able to use automated external defibrillators (AEDs). These electrical devices enable even trained lay providers to give a defibrillatory shock to patients in cardiac arrest when necessary. Placement of AEDs in locations such as airports, casinos, public buildings, and, most recently, schools has contributed greatly to the survival of many people in sudden cardiac arrest, including children.

Care providers such as pediatricians, who might encounter seriously ill or injured children in their practice setting, should also be trained in the principles and skills of pediatric advanced life support. Such training includes proper recognition of seriously ill patients, the proper interventions for preventing a child from developing respiratory or cardiopulmonary arrest, and the skills necessary to provide full resuscitation if arrest ensues. The AHA, in conjunction with the AAP, has developed excellent and comprehensive pediatric advanced life support courses, which are available in AHA training centers around the world.

Finally, given the importance of early BLS and electricity in out-of-hospital pediatric arrest, these skills must be integrated into a community-wide emergency response plan that deals with children. Because children spend so much time in the school system, schools especially should have an emergency response plan in place, coordinated with the local emergency medical system, and with medical direction from pediatricians or family practitioners.

### Specific Recommendations

In 2015, an international group of resuscitation experts reviewed the world literature on CPR for the fourth time (the initial international review was in 2000) and developed a global consensus and conclusions on what types of resuscitation treatments have been shown to be effective in neonates, children, and adults (2015 International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations, available at [www.circ.ahajournals.org/content/132/16\\_suppl\\_1.toc](http://www.circ.ahajournals.org/content/132/16_suppl_1.toc)).

Subsequently, similar to other resuscitation groups around the world, the AHA published formal practice guidelines based on these scientific recommendations and incorporated them into their courses. These practice guidelines were also published in the journal of the AHA, *Circulation*, available at [circ.ahajournals.org/content/132/18\\_suppl\\_2.toc](http://circ.ahajournals.org/content/132/18_suppl_2.toc).

The recommendations also emphasize the importance of following guidelines established by the US Occupational Safety and Health Administration (OSHA) to prevent transmitting disease from the victim to the rescuer, and they advocate the use of gloves and mechanical

ventilation equipment, including resuscitative masks, that divert expired air away from the rescuer.

### Basic Life Support

The AHA algorithm for pediatric BLS by health care providers is depicted in Figure A-1 and outlines the steps to be taken in providing pediatric basic CPR. Note that use of a mobile device to summon help is included. In addition, Table A-3 describes the BLS maneuvers and how they may differ among adults, children, and infants.

#### Step 1: Determining the Presence of Cardiac or Respiratory Arrest

If the child is unresponsive, the rescuer should shout for help and activate the Emergency Response System by mobile device (cell phone) if possible, requesting a defibrillator (either an AED or a manual defibrillator). Next, the rescuer should quickly check for breathing (gaspings is not considered breathing) with simultaneous checking for a pulse for no longer than 10 seconds. If there is no breathing but the pulse is definitely present, rescue breathing should be started at a rate of between 12 and 20 per minute. If both breathing and pulse are absent, the patient should be considered to be in cardiac arrest and chest compressions begun immediately. If nobody else is present, and if the length of time the child might have been in cardiac arrest or respiratory arrest is unknown, the rescuer should perform basic CPR for about 2 minutes before calling 911 (*phone FAST*). If the child is witnessed to have a sudden, unexpected cardiac arrest, ventricular fibrillation or ventricular tachycardia is highly likely, and obtaining a device that can defibrillate the child as quickly as possible is of paramount importance. Even before basic CPR is begun and if only a single provider is present, an immediate call to 911 or an equivalent emergency response system should be made to obtain the device and those who are trained in its use (*phone FIRST*).

#### Step 2: Checking the Pulse

For children older than 1 year, the carotid artery just lateral to the trachea or the femoral artery just below the inguinal ligament midway between the anterior iliac spine and the pubic tubercle should be palpated; for children younger than 1 year, the brachial artery in the upper medial arm should be palpated. Pulse checks are not recommended for the lay provider because they are often misinterpreted, resulting in withholding of cardiac compressions when they are indicated.

#### Step 3: Cardiac Compressions

Cardiac compressions should be started as soon as it is determined that there is no pulse (ventilations should not be initiated until 15–30 compressions have been given). For a child older than approximately 1 year, the heel of one hand should be placed on the lower sternum (avoiding the xiphoid process). The heel of the other hand may be placed over the first so as to have sufficient strength to compress the chest to approximately one-third to one-half of its anterior-posterior diameter. The child must be placed on a firm surface (backboard if the child is in a bed) so that the

ability to compress the chest adequately is not compromised. Compressions should be performed at a rate of at least 100, but no more than 120, compressions per minute, with attention paid not only to the depth of compression, but also to the adequacy of chest recoil after each compression. The heel of the hand should virtually come off the chest after each compression so that the chest can re-expand fully and the heart can fill with blood. The adequacy of chest compressions may be determined by ensuring that a femoral pulse can be felt with each compression; if the child has an arterial line, the intra-arterial pressure generated by each compression can be seen directly. The basic premise is to *push hard and push fast*. However, if compressions are performed too quickly, time may be inadequate for recoil of the chest, with failure of the heart to refill with blood because of inadequate venous return (which occurs during the recoil phase).

In infants, the optimal technique for chest compressions is to place both thumbs immediately below a line drawn between the 2 nipples (nipple or intermammary line) and encircle the chest with the palms and fingers of the hand, so that the fingers overlie the back. Compressing or squeezing the chest in this manner has been shown to result in better cardiac output than the long-taught 2-finger method, in which the third and fourth fingers are used to compress the anterior chest in the same location. The latter technique can be used if there is only 1 rescuer; however, with 2 rescuers, the chest encircling technique should be used.

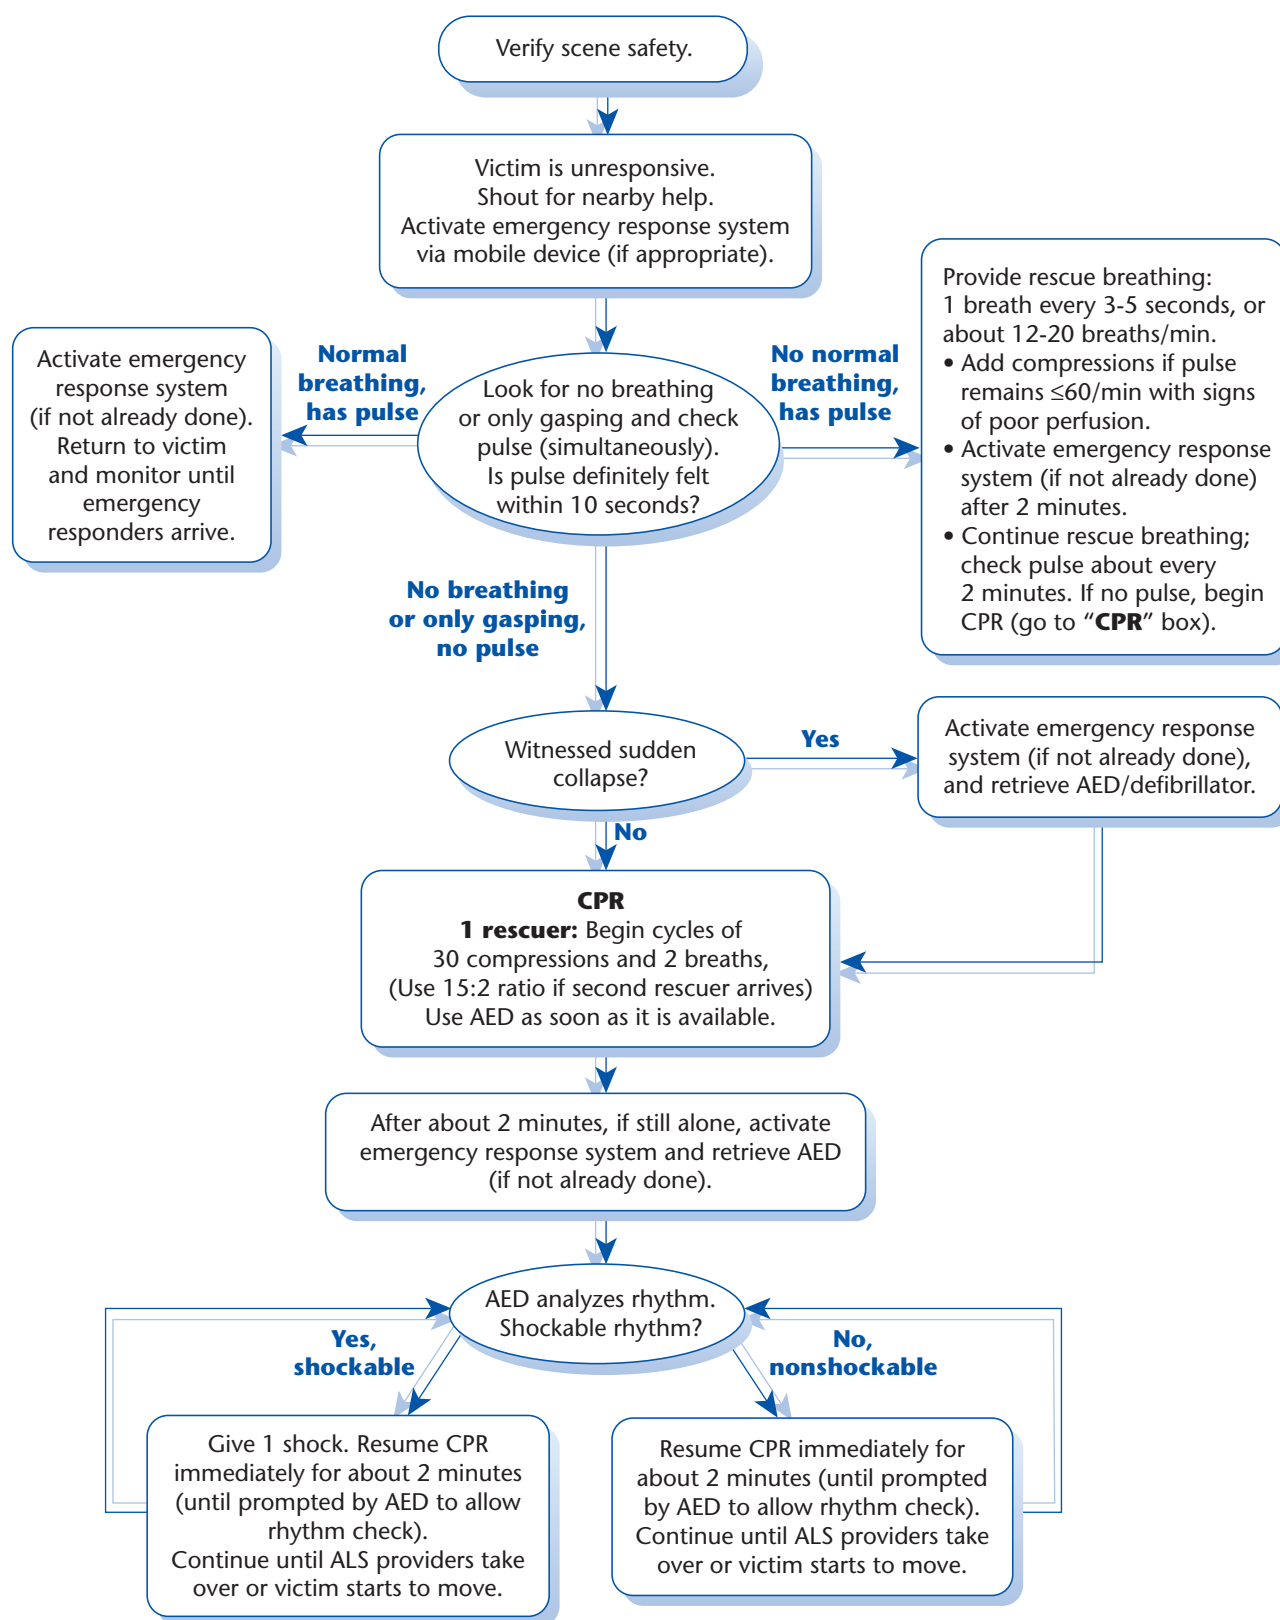

Compression of the chest is performed to enhance cardiac output, including coronary artery flow, either by direct cardiac compression (infants) or via a thoracic pump mechanism (blood flows out of the chest, heart, or aorta during compression and into the chest and heart during recoil). Therefore, attention to both the compression and recoil phases is important.

Since it is critically important for compressions to be done optimally (adequate depth, adequate rate, and adequate recoil) and with as little interruption as possible (goal: 80% of CPR time should be devoted to compressions), sensing devices interposed between the rescuer's hands and the chest wall are now available with integration of information about the depth, rate, and recoil into the monitor with visual and auditory feedback to the rescuer about compression adequacy.

In intubated patients in cardiac arrest, it is strongly recommended by the AHA that a capnograph be attached to the ET tube to measure end-tidal  $\text{PCO}_2$ . If it is less than 10 to 15 mm Hg, cardiac compressions should be done deeper, faster, and with better chest recoil, with a goal of 20 mm Hg. A sudden increase to a normal  $\text{PCO}_2$  indicates return of spontaneous circulation; CPR should be stopped and a rhythm check done.

#### Step 4: Opening the Airway and Initiating Ventilation

Once 30 compressions (single rescuer) or 15 compressions (2 rescuers) have been performed, the airway should be opened by tilting the head back slightly by pushing on the forehead with one hand and pulling

**Figure A-1** BLS health care provider pediatric cardiac arrest algorithm for the single rescuer—2015 update. (From American Heart Association. 2015 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. **Table A-3** Summary of High-Quality CPR Components for BLS Providers

COMPONENT	ADULTS AND ADOLESCENTS	CHILDREN (AGE 1 YEAR TO PUBERTY)	INFANTS (AGE LESS THAN 1 YEAR, EXCLUDING NEWBORNS)
Scene safety	Make sure the environment is safe for rescuers and victim		
Recognition of cardiac arrest	Check for responsiveness No breathing or only gasping (ie, no normal breathing) No definite pulse felt within 10 seconds (Breathing and pulse check can be performed simultaneously in less than 10 seconds)		
Activation of emergency response system	If you are alone with no mobile phone, leave the victim to activate the emergency response system and get the AED before beginning CPR Otherwise, send someone and begin CPR immediately; use the AED as soon as it is available	<b>Witnessed collapse</b> Follow steps for adults and adolescents on the left <b>Unwitnessed collapse</b> Give 2 minutes of CPR Leave the victim to activate the emergency response system and get the AED Return to the child or infant and resume CPR; use the AED as soon as it is available	
Compression-ventilation ratio <i>without advanced airway</i>	<b>1 or 2 rescuers</b> 30:2	<b>1 rescuer</b> 30:2 <b>2 or more rescuers</b> 15:2	
Compression-ventilation ratio <i>with advanced airway</i>	Continuous compressions at a rate of 100–120/min Give 1 breath every 6 seconds (10 breaths/min)		
Compression rate	100–120/min		
Compression depth	At least 2 inches (5 cm) <sup>a</sup>	At least one-third AP diameter of chest About 2 inches (5 cm)	At least one-third AP diameter of chest About 1½ inches (4 cm)
Hand placement	2 hands on the lower half of the breastbone (sternum)	2 hands or 1 hand (optional for very small child) on the lower half of the breastbone (sternum)	<b>1 rescuer</b> 2 fingers in the center of the chest, just below the nipple line <b>2 or more rescuers</b> 2 thumb-encircling hands in the center of the chest, just below the nipple line
Chest recoil	Allow full recoil of chest after each compression; do not lean on the chest after each compression		
Minimizing interruptions	Limit interruptions in chest compressions to less than 10 seconds		

<sup>a</sup>Compression depth should be no more than 2.4 inches (6 cm).

AED, automated external defibrillator; AP, anteroposterior; BLS, basic life support; CPR, cardiopulmonary resuscitation.

the chin or mandible forward with the other hand (head tilt/chin lift maneuver). In all trauma patients, or if the head tilt/chin lift maneuver is unsuccessful in patients without trauma, a jaw thrust should be performed instead by placing the index and third fingers of both hands under the angle of the mandible and pushing anteriorly or upward. (The neck should be kept in a neutral position if the child is a trauma victim.) If the jaw thrust is unsuccessful in trauma patients and the airway is still not open, a head tilt/chin

lift maneuver may be performed carefully, but only sufficiently to allow air entry with ventilation. In an infant, no hyperextension of the neck should occur, given that this action may collapse the very compliant airway or trachea. Instead, the infant's head position should be neutral and placed in the sniffing position.

Mouth-to-mouth or bag-mask ventilation must be instituted by giving two 1-second breaths, each just effective enough to make the chest rise. With an infant, the rescuer should give mouth-to-mouth

ventilation by covering the mouth and nose of the infant with the rescuer's own mouth; in the older child, the rescuer pinches the nose and seals the patient's mouth with the rescuer's own mouth. The rescuer delivers puffs of air given over 1 second, breaking the mouth seal after each puff to allow the patient to exhale. The breath should be just sufficient to cause the chest to rise, given that excess ventilation volume and time may interfere with venous return. Using this volume of air and puffs prevents gastric distention in the patient and should still allow air to enter the lungs freely. The most common reason for inadequate air entry is improper head positioning resulting in a partially obstructed upper airway; it should be readjusted and mouth-to-mouth breathing repeated.

If a pocket mask or a ventilation bag (with 100% oxygen) with mask is used, the mask must fit properly over the nose and mouth with a tight seal so that no leakage of air (and thus an inability to provide an adequate breath) occurs.

Anterior cricoid pressure (using 1 fingertip in infants or the thumb and index finger in children to put pressure on the anterior trachea just below the cricothyroid membrane) is *no longer recommended* in the 2015 AHA guidelines. During basic CPR as a standard maneuver to occlude the proximal esophagus and prevent entry of air into the stomach. However, it may be considered if there is inadequate air entry and to help visualize the glottis in infants and young children during ET intubation.

If the chest still does not rise even after proper positioning to open the airway and attempts at ventilation, a foreign body lodged in the upper airway should be suspected. The rescuer should perform a Heimlich maneuver (abdominal thrusts) in children over 1 year of age, or back blows alternating with chest thrusts in infants. In children older than 1 year, the child is positioned supine, and the rescuer performs rapid and short upward pushes (abdominal thrusts) with the heel of the hand in the central upper part of the child's abdomen (below the xiphoid process but above the umbilicus) until the object is expelled. The examiner should inspect the mouth every 5 to 10 abdominal thrusts to see if a foreign body can be manually removed. Blind finger sweeps should not be performed because the risk of pushing an object down further is increased. If the patient remains unresponsive, CPR should be resumed. In children less than 1 year (infant), the infant is straddled over the rescuer's forearm, the head positioned lower than the trunk, and the jaw held open by the rescuer's fingers, and up to 5 back blows with the heel of the hand are delivered between the shoulder blades. If this action does not remove the foreign body, the infant should be turned over so that the head, neck, and back are well supported on the rescuer's forearm. Up to 5 chest thrusts similar to cardiac compressions, but deeper, should be given. Alternate 5 back blows with 5 chest thrusts until the foreign body is expelled (the mouth is inspected periodically). If no response occurs, basic CPR is continued.

In children who have a tracheostomy and who are not breathing or are unresponsive, ensuring a patent airway is essential. Attempts to provide breath via

mouth-to-tracheostomy or bag-to-tracheostomy should be initiated. If no chest rise ensues, the tracheostomy may be obstructed or dislodged. Immediate tracheal suctioning should be performed. However, if tracheal suctioning cannot be accomplished rapidly, the tracheostomy should be removed, a small roll should be placed under the shoulders (if available), and either a fresh tracheostomy should be inserted or a breath given by sealing the mouth over the stoma and blowing into it. If no chest rise is observed, the stoma should be occluded and breaths provided via the nose or mouth.

**COMPRESSION/VENTILATION RATIO.** Given that current science has shown that continuous and effective cardiac compressions with minimal interruptions are necessary to maintain coronary blood flow to the myocardium, a compression/ventilation ratio of 30 compressions to 2 ventilations should be used for single-rescuer CPR for all ages except neonates who remain hospitalized after birth in neonatal intensive care units. Although this ratio is to be maintained for single- and 2-rescuer CPR in adults and children who have reached puberty, as well as for lay providers who are performing CPR in all age groups, a ratio of 15 compressions to 2 ventilations is recommended when 2 health care providers are providing basic CPR to a prepubertal child (approximately 12 years of age or younger), including infants.

Because maintaining adequate chest compressions for a long time period is difficult for an individual, compressors should be changed approximately every 2 minutes.

Although these ratios should be maintained in an infant or child who does not have a definitive airway, once an ET tube is in place, continuous compressions should be maintained at a rate of between 100 and 120 compressions per minute and ventilations at a rate of 10 ventilations per minute (1 every 6 seconds) without an effort to coordinate them.

### Step 5: Defibrillation/AED Use

Defibrillation of a shockable rhythm should occur within 3 minutes of the event for best results. Thus, if the defibrillator or AED has arrived, pads should be placed immediately on the patient and an analysis of the rhythm should be performed. If a shock is advised by the AED or if the manual defibrillator shows a shockable rhythm (ventricular fibrillation or ventricular tachycardia), a single shock should be delivered and CPR should be resumed immediately for another 2 minutes before another rhythm check is undertaken. If there is only a single rescuer, after 2 minutes of CPR the rescuer should try to alert the emergency response system and attempt to get a defibrillator.

### Step 6: Rhythm Checks

A rhythm check should be done after every 2 minutes of CPR to determine if there is a shockable rhythm or if a perfusing rhythm has returned. If there is a perfusing rhythm, a pulse check should be done before continuing with CPR.

### Automated External Defibrillation

Although most cardiac arrests in children are from noncardiac causes, a substantial number of children

with out-of-hospital cardiac arrest (15%–20%) are known to have sudden onset of ventricular fibrillation or ventricular tachycardia. These children have a variety of conditions, including prolonged QT interval or other channelopathies, hypertrophic cardiomyopathy, myocarditis, repaired congenital heart defects with postsurgical dysrhythmias, toxic ingestions, and *commotio cordis*. The last of these conditions is a sudden episode of ventricular fibrillation or ventricular tachycardia resulting from a sharp blow to the chest, such as might occur in baseball, lacrosse, hockey, or other sports during which flying objects might impinge on the chest. Because these sports are played in many high schools around the country, attention has been increasingly focused on ways to treat ventricular fibrillation arrests in children within the 3 minutes recommended by the AHA. As demonstrated in adult studies and seen in many individual patients, including children and adolescents, the best outcomes from sudden cardiac arrest occur when bystander CPR is initiated immediately coupled with early defibrillation, preferably within 3 minutes of cardiac arrest. Given that this combination has been shown to result in 50% to 60% or better survival from sudden cardiac arrest (usual survival is <5%) in adults, widespread availability of both bystander CPR training and AEDs has been strongly encouraged. In fact, as the use of AEDs has become more widespread and available, training in the use of these devices has been added to many of the basic CPR courses taught to laypersons. Given the increased recognition that children also experience cardiac arrest from ventricular fibrillation, efforts have been initiated to develop AEDs that are safe to use in children. In addition, because sudden episodes of ventricular fibrillation in adolescents are known to happen in schools, especially during athletic activities, making AEDs available in schools has been advocated. New York State took the lead in this effort by passing a law in 2001 requiring AED devices to be available in all schools with more than 500 students, giving specific instructions as to their location and quantity, and the need to have them available at all school sports events.

An AED device is a portable system consisting of chest pads, a cable, a biphasic current-generating device using (generally) a fixed voltage, a computer that can sense and analyze ECG rhythms, and a voice generator for providing appropriate instructions to the operator. Audible instructions to the operator are simple and sequential, including a sequence such as “Attach pads”; “Insert connector”; “Analyzing rhythm. Do not touch the patient”; “Shock advised [or not advised]”; “Charging”; “Press the orange button”; “Shock delivered”; and “If necessary, start CPR.” Although previously AEDs were programmed to deliver 3 shocks in succession, they have been reprogrammed to reflect the AHA guidelines that only 1 defibrillation shock should be given each time.

Although AEDs have a fixed voltage of between 120 and 200 joules (much more than the 2–4 joules/kg recommended for children), they can be used safely in children and even infants with some adaptations. Based on the 2010 International Consensus on Cardiopulmonary Resuscitation and Emergency

Cardiovascular Care Science with Treatment Recommendations, the AHA has made the following recommendations:

1. For patients from 1 to 8 years old (up to 25 kg), an AED that is equipped with pediatric cables (containing a resistor limiting the shock to 50 joules), and that shows both a high degree of specificity (100%) for recognizing normal rhythms and sensitivity for diagnosing shockable rhythms, should be used if at all possible. If these features are not available, an AED with adult cables may be used (gives 150–200 joules).
2. For patients weighing 25 kg or more (over 8 years of age), a standard AED should be used.
3. For infants, there is now sufficient scientific evidence to recommend a pediatric-capable AED and, if this is not available, use of a standard AED.

Although not well tested as to improving outcomes, a significant number of hospitals and medical centers are beginning to place AEDs on general inpatient units (including children’s units), lobbies, and cafeterias, among other locations, as it becomes clearer that trained nonphysician staff can use these devices effectively and respond more quickly than conventional hospital code teams led by physicians.

### Advanced Life Support

When pediatric BLS measures, such as CPR, are ineffective in resuscitating and stabilizing affected infants and children, advanced life support should be initiated immediately using the most current AHA guidelines. Advanced life support includes improved airway access and management, administration of oxygen, vascular access, administration of fluids and electrolytes, and drug therapy. To implement these measures, the physician must be familiar with the ranges of weight and vital signs for children (see Table A-2) and the guidelines for use of resuscitation equipment of various sizes according to the patient’s age and weight (Table A-4). Use of a length-based pediatric emergency tape to determine appropriate drug doses and equipment based on size has been validated and is useful for children, particularly those weighing less than 25 kg. The child’s approximate weight is determined by measuring the child’s recumbent length.

### Respiratory Management

The purpose of respiratory management is to provide and maintain adequate oxygenation and ventilation to meet the body’s metabolic requirements.

**OXYGEN ADMINISTRATION.** The correction of tissue hypoxia is fundamental to the management of all critical illness and injury and also to resuscitation. Tissue oxygenation depends on adequate oxygen delivery into the alveolar spaces of the lungs, ability to bind to hemoglobin as blood circulates through the alveolar capillaries, an adequate amount of hemoglobin in the blood, an adequate cardiac output, and ability to release oxygen from hemoglobin to the tissues. Thus, even if an airway with appropriate ventilation exists, a sufficient supply of oxygen must still be available to bind to hemoglobin, particularly when tissue oxygen demands are significant. Normally,

Cuff, cuffed endotracheal tube; ETT, Endotracheal tube

<sup>a</sup>If cuffed tube is used, decrease size by 0.5 mm.

when a person breathes room air (21%  $\text{FiO}_2$ ), the  $\text{PO}_2$  is approximately 100 mm Hg. Mouth-to-mouth breathing delivers only 16%  $\text{FiO}_2$  and results in an intra-alveolar oxygen tension ( $\text{PO}_2$ ) of only 64 mm Hg. Given a higher oxygen demand in critical illness, oxygen is indicated in any situation in which a significantly inadequate amount of oxygen is bound to hemoglobin (oxygen saturation less than approximately 90%–91%), tissue hypoxia is suspected even in the presence of a high oxygen saturation (eg, if there is poor cardiac output or severe anemia), or respiratory distress is significant.

Oxygen can be administered by blow-by nasal cannula (up to 50%–60%  $\text{FiO}_2$ ), face tent, partial rebreather mask (up to 70%  $\text{FiO}_2$ ), non-rebreather mask (90%–100%  $\text{FiO}_2$ ), or a Venturi mask with fixed concentrations of oxygen based on flow. If the child has any possibility of a serious illness or injury or is being resuscitated from a respiratory or cardiac arrest, 100% oxygen should be provided by either a non-rebreather mask (making sure the reservoir bag is at least partially full); with a free-flowing oxygen anesthesia bag with mask fitting snugly over the child's nose or mouth; or with positive-pressure breaths, if necessary, with a self-inflating bag and 10- to 15-L/min flow of 100% oxygen and a reservoir (most do not deliver oxygen spontaneously unless the bag is compressed). Although for acute management and a short time period, nonhumidified, cold oxygen is adequate, for longer-term oxygen administration, the oxygen should be humidified and preferably warmed to room temperature. If assisted ventilation is necessary to provide oxygen and the child is breathing, the breaths should be synchronized with the child's so that the risk of gastric inflation is reduced. When a self-inflating bag is used, the pop-off valve should be occluded, because the pressures needed to ventilate the lungs may exceed the valve's limit (usually set at approximately 45 cm  $\text{H}_2\text{O}$  pressure).

**AIRWAY ADJUNCTS.** For children who have inadequate air entry into the chest despite head tilt/chin lift or jaw thrust maneuver, airway adjuncts may be helpful. Nasopharyngeal and oropharyngeal airways can stent open the upper nasopharynx or oropharynx; an ET tube can provide an unobstructed airway directly from the nose or mouth into the trachea, and a laryngeal mask airway device, placed into the hypopharynx or upper esophagus, can effectively direct oxygen through the glottis without it going into the esophagus (the inflated cuff obstructs the upper esophagus).

**OROPHARYNGEAL AND NASOPHARYNGEAL AIRWAYS.** An oropharyngeal airway may be used in an unconscious patient to prevent the tongue from occluding the pharynx. It should not be used in conscious patients, because significant gagging and vomiting may occur. When placed next to the child's mandible, a proper-sized oropharyngeal airway should extend from the anterior gums or incisors (flange) to the angle of the jaw (tip). Insertion is accomplished by depressing the tongue with a tongue depressor and inserting the airway into the mouth or pharynx in the position of function. If the airway is too large, it may impinge on the epiglottis and close the airway or injure it; if the airway is too small, it may push the tongue back into the oropharynx and occlude it.

If the patient is semiconscious, or if placing an oropharyngeal airway is impossible (eg, during grand mal status epilepticus), a nasopharyngeal airway may be inserted. The proper length of a nasopharyngeal airway is determined by measuring the length from the tip of the nose to the tragus of the ear, and the width is similar to the width of the nares. Care must be taken during insertion because hypertrophied adenoidal tissue is common in young children and can bleed when traumatized. Because obstruction of nasopharyngeal airways with mucus and blood can occur, periodic suctioning with a flexible suction catheter should be performed to maintain patency.

**SUCTIONING.** Suctioning of the oropharynx should be accomplished quickly and with a large-bore suction device. Yankauer or tonsil suction devices are rigid but available in both adult and pediatric sizes. They are designed to suction vomitus and other large secretions out of the posterior pharynx quickly. Large (14 French) flexible suction catheters can be used in infants to accomplish this function, but flexible suction catheters are intended primarily for nasopharyngeal and ET suctioning. Generally, suctioning should be performed for no longer than 5 to 10 seconds because vagal-induced bradycardia from stimulating the posterior pharynx may occur and oxygen may be removed by suctioning via the ET tube. Continuous monitoring of the heart rate during suctioning in a critically ill patient is useful for early recognition of bradycardia.

**Endotracheal Intubation of Airway.** Although ET intubation is critically important in a child who is in respiratory failure (inadequate ventilation or oxygenation), it is less urgent in a child who can be easily oxygenated and ventilated either on his own with supplemental oxygen, by bag-mask ventilation, or by noninvasive ventilation (eg, Bilevel Positive Airway Pressure [BiPap]). Particularly in a child who is in cardiac arrest, persistent and uninterrupted (no more than 10 seconds) cardiac compressions are more important than ET intubation (compressions have to be interrupted while intubation proceeds) as long as ventilation and oxygenation remain adequate. In addition, although resuscitation medications (lidocaine, epinephrine, atropine, naloxone) can be given through the ET tube if no other route is available, resuscitation medications by intravascular or IO routes are preferable. Medications given down the ET tube are variably absorbed, and there is little scientific evidence to indicate proper dosing. However, if a child cannot be oxygenated adequately despite high concentrations of oxygen, ET intubation should be considered early.

ET intubation should be accomplished by the available person with the most intubation expertise. The procedure should be preceded by oxygenation with 100%  $\text{FiO}_2$ , either by non-rebreather mask or by assisted ventilation with a bag-mask device delivering 100%  $\text{FiO}_2$ . If the patient is awake, sedation and muscle relaxants should be administered by persons properly qualified to perform this task to enable safe and efficient intubation. Of note, etomidate is an excellent drug for sedating a child who needs to have an ET tube placed, because it causes little hemodynamic instability. However, it should *not* be used if there is a possibility that the child has sepsis, because even a single dose can

significantly depress adrenal function, resulting in hypotension and hypocortisolism for 24 to 48 hours. If the child is in cardiac arrest, medications are not necessary.

Before intubation, the operator should put on gloves, a mask, and preferably goggles to prevent self-contamination with secretions. Equipment at the bedside should include a working and proper-sized bag-mask device; oropharyngeal suction equipment (Yankauer); ET suction catheters to suction out the ET tube; a working and proper-sized laryngoscope blade; proper-sized ET tubes, including cuffed tubes; a stylet; an end-tidal PCO<sub>2</sub> detector or capnometer or capnograph; and tape or benzoin. For the potentially difficult airway, ancillary equipment should be considered, such as laryngeal mask airway devices, a videolaryngoscope, ET bougies, and a needle cricothyrotomy setup.

The ET tube should be translucent, of uniform diameter (not tapering), and equipped with a standard 15-mm adapter; preferably the tube should have distance markers and an opening on its side wall (Murphy tube, not in neonates), as well as at its end. Cuffed ET tubes may be used at all ages, but a cuffed tube size that is 0.5 to 1 mm less than an orotracheal tube for young children should be considered. An air leak with an uncuffed ET tube should be present when a breath is given at 20 cm H<sub>2</sub>O pressure; if it is not, the tube is too large and should be replaced with a smaller tube. Although the proper-sized tube should be determined by checking a size-based chart or tape, the proper-sized *uncuffed* ET tube may also be determined by its internal diameter as follows: term neonate: 3.0 mm; 6-month-old: 3.5 mm; 1-year-old: 4.0 mm; 1- to 12-year-old: [(age in years ÷ 4) + 4] mm. The depth of the ET tube is determined by multiplying the size of the tube by 3 and having this number at the gum line/teeth. If a *cuffed* ET tube is used, the size of the tube is determined as follows: up to 1 year: 3.0 mm; 1 to 2 years: 3.5 mm; after 2 years: [(age in years ÷ 4) + 3.5] mm. Cuffed ET tubes may be used in children younger than 8 to 10 years who are in a hospital setting, because they have been shown to be as effective and safe as uncuffed ET tubes (class 1). Whether such is the case in an out-of-hospital setting is unknown.

Straight-blade laryngoscopes to visualize the larynx are preferred in children, given that the larynx is quite anterior and the glottis may not be seen unless the epiglottis is lifted. Before laryngoscopy is begun, the examiner should check the equipment and the light source. Attempts at ET intubation should not exceed 30 seconds, and the heart rate and oxygenation should be monitored during the procedure. Bradycardia below 80 bpm in a neonate or 60 bpm in a child mandates interruption of the procedure and administration of 100% oxygen by face mask and bag. The ET tube should be passed into the trachea to a length that places the distance marker at the level of the vocal cords.

Once intubation has been established, the ET tube should be held securely in position, an end-tidal PCO<sub>2</sub> detector (Figure A-2) attached, and the patient ventilated with a bag (100% oxygen).

The ET tube position is confirmed by observing symmetrical movements of the chest, auscultating the apical and axillary lung fields to detect bilateral breath

**Figure A-2** End-tidal CO<sub>2</sub> detector.

sounds, auscultating over the stomach to ensure that air entry sounds are absent, demonstrating persistent evidence of carbon dioxide exhalation (color change) after 6 breaths. A colorimetric end-tidal PCO<sub>2</sub> detector is not reliable in the presence of cardiac arrest (insufficient PCO<sub>2</sub> delivered to the lungs) and should not be used as the primary way to confirm proper placement of the ET tube. Visual inspection of the vocal cords for evidence that the ET tube is in the proper location will be more helpful in this situation. However, during a cardiac arrest, a capnograph should be attached to the ET tube for a continuous objective readout of exhaled PCO<sub>2</sub>. This will allow for better assessment of the adequacy of cardiac compressions.

Asymmetrical right-sided breath sounds usually indicate intubation of the right main bronchus. When this occurs, the tube should be withdrawn until breath sounds are heard bilaterally; the ET tube should then be withdrawn another 1 to 2 cm (depending on the size of the patient; an infant has a very short trachea) to ensure a midtracheal position, keeping in mind the optimal depth of the tube by the measurement at the gums (3 times the width of the ET tube). The final position of the ET tube must be confirmed by chest radiograph.

A properly placed tube, but inadequate chest expansion, may indicate that the tube is too small or that a large laryngeal air leak is present (detected by auscultating the anterior neck), the *pop-off* valve on the ventilator bag is not disabled so that air escapes when the preset pressure is reached, the bag-valve device leaks, or the breath administered is too small.

The position of the tube should be verified by noting the distance marked on the tube at the gums; it should be secured to the patient's face with benzoin and tape. Its position should be assessed frequently by observing

chest wall expansion, listening for bilateral breath sounds, and noting improvement of color and perfusion, obtaining blood gas values, and checking pulse oximeter readings.

Esophageal detector devices may be used for confirmation of appropriate ET tube placement in children who weigh at least 20 kg and who have a perfusing rhythm. However, given that no information about the efficacy of these devices in children who are in cardiac arrest is available, they are not recommended for use in this situation.

Once an infant or child in cardiac arrest has had an ET tube placed, 1-second ventilations should be given no faster than 8 to 12 breaths per minute. Excessive ventilation may be detrimental to outcome from cardiac arrest because positive-pressure ventilation interferes with the venous return necessary for refilling of the heart during the recoil phase of compressions. Once spontaneous circulation has been re-established, the rate of ventilations should be 12 to 20 breaths per minute for all ages.

Drugs may be administered through the ET tube while vascular access is sought. These drugs are lidocaine, epinephrine, atropine, and naloxone (LEAN). Double to triple the usual IV dose (diluted in 1 to 2 mL of 0.9% saline or followed by a 5-mL normal-saline flush) is administered through a catheter that has been passed beyond the ET tube as deeply as possible into the tracheobronchial tree. The dose of epinephrine, however, should be 10 times the IV dose (0.1 mg/kg using a 1:1,000 solution), except in neonates, where it may be 0.05 to 1 mg/kg. After the drug has been instilled, at least 5 manual positive-pressure breaths should be given to distribute the medication throughout the lung fields.

Even after an ET tube has been placed successfully, sudden problems can occur with the airway with inadequate oxygenation and ventilation. An easy way to evaluate the cause of the problem is to use the mnemonic DOPE: Displacement, Obstruction, Pneumothorax, and Equipment. The gas delivery system (if the child is being mechanically ventilated) should be disconnected, and the patient should receive manual ventilation by means of a resuscitation bag and use of 100% oxygen. Auscultation should be used to determine the tube's position and patency. Decreased resistance to inflation occurs when the ET tube has been misplaced into the esophagus, with a gurgling sound often present. Corroboration of tracheal placement of the ET tube can be accomplished with an end-tidal PCO<sub>2</sub> detector in a nonarrested patient. If the tube has slipped down one of the main bronchi (usually the right), no or diminished breath sounds on the opposite side will be heard. If obstruction is the problem, poor breath sounds, a lack of chest movement, and increased resistance to inflation are observed. The ET tube can be either kinked or obstructed. If obstructed, 1 to 3 mL of saline should be instilled, bagging should be attempted to irrigate the tube and break up mucous plugs, and then suctioning of the ET tube should be performed for 5 to 10 seconds. After suctioning, the breath sounds, airway resistance, and adequacy of chest movements should be re-evaluated. If proper positioning and adequate manual ventilation of the ET

tube are ensured and no asymmetric breath sounds are heard, problems with equipment, including the oxygen source, should be considered. If ventilation cannot be re-established with chest rise and improved oxygenation, the ET tube should be removed, the child should be ventilated with 100% oxygen, and a new ET tube should be inserted. If the child has asymmetric breath sounds, a pneumothorax may be present on the side without breath sounds, and urgent needle thoracentesis needs to be considered. A needle catheter is placed in the second intercostal space in the midclavicular line on the side without breath sounds, and the catheter is aspirated with a syringe. Aspiration of air suggests a pneumothorax, and plans for chest tube insertion should be initiated immediately.

**CRICOTHYROTOMY.** If ET intubation is not an option or cannot be accomplished, and if no air entry is attained after airway positioning and ventilation, a needle cricothyrotomy may be attempted. A roll is placed underneath the shoulder, and the head is hyperextended so that the larynx is brought anteriorly. A large-bore needle catheter (14–16 gauge) is placed with its bevel caudally directed, midline, just below the thyroid cartilage in the cricothyroid membrane. A syringe is attached, and while the needle-catheter is advanced, continuous aspiration is performed. Entrance into the trachea is indicated by aspirating air, and the catheter should be advanced, similar to cannulating a blood vessel. Either the adapter from a small ET tube can be attached directly to the catheter hub or the barrel of a 3-mL syringe can be attached, with an oxygen tube under high pressure inserted into the barrel. By providing a continuous inflow of oxygen through the catheter, oxygen can be supplied for a short time period (<20 minutes). Ventilation cannot occur through this type of setup, and a surgical tracheostomy should be performed as soon as possible.

In patients younger than 8 years, airway obstruction may occur at the cricoid ring, the narrowest portion of the larynx in this age group. Because the ring is located below the cricothyroid membrane, cricothyrotomy may not be effective in establishing an airway.

**LARYNGEAL MASK AIRWAY DEVICE.** A laryngeal mask airway device (Figure A-3) is placed blindly into the hypopharynx or upper esophagus so that air or oxygen can be directed anteriorly into the glottis, but will not enter the stomach. These airway devices are available in different sizes, are suitable even for neonates, and may be useful for children who require an artificial airway for short-term management or who are difficult to intubate (eg, children with mandibular hypoplasia). Children seem to have a higher incidence of complications with these devices than adults, and only trained providers should insert them. In addition, they have not been tested for safety or efficacy in a prehospital (emergency medical system) setting or in patients in cardiac arrest (class IIb).

### Circulatory Management

The basic purpose of circulatory management is to maintain sufficient cardiac output to deliver appropriate amounts of oxygen and other nutrients to the

**Figure A-3** Laryngeal mask airway.

tissues, especially to the vital organs—the heart, the brain, the kidneys, and the splanchnic bed.

Cardiac output and perfusion depend on an adequate amount of preload (end diastolic volumes of the heart), good cardiac contractility and heart rate, and appropriate afterload (the resistance against which the heart has to eject its blood). All circulatory management is directed toward optimizing each of these factors, starting with preload, then addressing cardiac contractility or rate, and finally manipulating afterload.

**VASCULAR ACCESS.** Given that circulatory management in a critically ill patient involves the use of both fluids and medications, venous access should be established as quickly as possible. Antecubital veins—the lesser saphenous vein just above the medial malleolus and external jugular veins—are excellent veins to attempt if more peripheral hand and foot veins are not palpable. Scalp veins are generally not recommended, because insertion into them often will interfere with airway management, and even external jugular veins may complicate simultaneous airway management. In patients who are in cardiac arrest or decompensated shock, or who require rapid initiation of infusion of fluids or medications, an IO line should be used if vascular access cannot be established after approximately 90 seconds. The IO space is a plexus of noncollapsible veins in continuity with the central venous circulation. Any type of fluid or medication may be infused through an IO line, including blood products, calcium, and glucose. Most providers will find placing an IO device faster and easier than cannulating a central vein, even when such a vein is accessible (eg, the femoral vein).

IO access may be obtained in patients of all ages, including newborns in the delivery room and adults. The most common site selected is the flat part of the proximal tibia, a few centimeters below the tibial tuberosity, but other sites for IO infusion include the distal tibia just above the middle malleolus, the distal part of the femur just above the patella, the anterior iliac crest, and, in older children, the proximal humerus. A line should not be placed in a fractured bone or in a bone in which an attempt at an IO line

has already been made. (If a hole exists into the bone from the previous attempt, fluid from a new line in that bone will leak out into the soft tissues.) The typical IO needle is 15 gauge in caliber, although in infants even 18- to 21-gauge spinal needles have been used. The needle should have a trocar or stylet within, so that bone fragments do not occlude the needle during placement. Battery-powered drills with preset needle depth are now available to allow for easier insertion.

Because resistance to flow via the IO route may be high, infusions may require pressure bags, pumps, or manual infusion by syringe. In addition, IO lines should be carefully secured, because they are easily dislodged. Constant assessment of the soft tissues at the site of the IO infusion device should also occur, given that dislodgement can result in significant extravasation. IO lines are only for short-term use and should be removed within 6 hours if at all possible to avoid a complicating bone infection.

**FLUIDS.** Most children who are in shock will have a deficit in intravascular volume because of lack of fluid from water losses (eg, diarrhea or excess urine output), from inadequate fluid intake, or from blood loss. Given the deficit in intravascular volume, these children will have a diminished preload and decreased cardiac output (stroke volume multiplied by heart rate/min). Rapid infusion of a 20-mL/kg bolus of fluid within 10 minutes with re-evaluation during and immediately after infusion will quickly determine whether lack of intravascular volume is the problem. In a child who shows signs of circulatory compromise with tachycardia, prolonged capillary refill, and decreased peripheral pulses, a response to such a rapid infusion with a decrease in heart rate and improved pulses and capillary refill suggests that preload was not adequate and now has improved. Further boluses of fluid may be warranted depending on the degree of improvement found. A child who is in hypovolemic shock often requires 40 to 60 mL/kg of fluid in the first hour of resuscitation and, occasionally, up to 100 to 200 mL/kg in the first few hours. A 3-way stopcock attached to a 20-mL or 60-mL syringe may be useful in pushing fluids with the aid of the syringe. Fluid resuscitation should be monitored by reassessing perfusion frequently. Fluid overload is detected by auscultating the chest for signs of pulmonary edema, palpating hepatomegaly, and noting the size of the heart on a chest radiograph. In hypovolemia, the heart is normal or small in size; in cardiogenic shock or fluid overload, it is usually enlarged.

The types of fluids available for volume expansion include the following:

1. Crystalloids—lactated Ringer's or 0.9% saline. Lactated Ringer's is often preferred because it contains less chloride than normal saline (134 mEq/L vs 154 mEq/L) and thus does not aggravate acidosis. Because only approximately one-third to one-fourth of crystalloids remain in the vascular space, approximately 3 to 4 times the deficit is required to restore plasma volume in the event of blood loss.
2. Colloids—albumin, fresh-frozen plasma, human plasma protein fraction. Colloids are never the fluids of first choice and should be used only for

specific indications or after at least 2 to 3 crystalloid boluses have been given without persistent effect. A 20-mL/kg dose of 5% albumin, a 4-mL/kg (1 g/kg) dose of 25% albumin, or a 20-mL/kg dose of fresh-frozen plasma may be used while assessing the perfusion in the patient continuously.

3. Packed red blood cells (10 mL/kg) should be given to a patient who is suspected of having significant or ongoing blood loss if 2 to 3 boluses of crystalloid do not improve perfusion persistently. If the child is a trauma victim, surgical consultation is mandatory, because expeditious evaluation for occult blood losses may be necessary (eg, exploratory laparotomy). Infusion pumps or mini-drip chambers should generally be used for infusion therapy. However, infusion pumps typically cannot infuse fluids more quickly than 1,000 mL/hr. If the goal is to give a 20-mL/kg bolus of normal saline to a 20-kg patient over 10 minutes, a rate of 2,400 mL/hr would be required. In such a case, a better approach would be to place a 3-way stopcock in the IV or IO line and manually infuse fluids in 60-mL aliquots, refilling the syringe repeatedly from the main saline supply bag. In addition, giving this amount of fluid using 2 or 3 IV or IO lines simultaneously should also be a consideration.

Dextrose is not administered in the initial resuscitative fluids unless hypoglycemia exists. In many critically ill children, the endogenous catecholamines are elevated, resulting in an increase in blood glucose. Hyperglycemia may induce an osmotic diuresis with more intravascular volume loss, and the hyperglycemia may also exacerbate neurologic injury.

**INOTROPIC AND VASOACTIVE DRUGS.** Even after preload has been corrected, the disease process causing circulatory compromise may affect contractility significantly, either from infectious agents or from metabolic factors. In these instances, providing inotropic support may be lifesaving. A variety of agents can provide inotropic support, along with concomitant effects on heart rate and on the peripheral circulation. The effects will vary from patient to patient and from drug to drug.

**DOPAMINE.** Dopamine is an endogenous catecholamine that is an immediate precursor of norepinephrine. At low doses (2–5 mcg/kg/min), it binds to dopamine receptors in splanchnic, coronary, and renal vascular beds, causing predominantly vasodilation and increased contractility with relatively little effect on heart rate and BP. At higher doses (6–12 mcg/kg/min),  $\beta_1$ -adrenergic effects (inotropic, chronotropic, and dromotropic) and  $\alpha$ -adrenergic effects (arterial and venous vasoconstriction) predominate, resulting in increased cardiac output and BP. At doses above 12 mcg/kg/min, vasoconstrictive effects dominate. The indications for use of dopamine at this dose are hypotension or poor peripheral perfusion in the presence of a stable rhythm and with adequate vascular volume.

A reasonable starting dose of dopamine for a patient in nonhypotensive shock is 5 to 10 mcg/kg/min. Infusion rates above 20 mcg/kg/min are not useful, because the effect is predominantly vasoconstrictive and because more selective drugs are available to use for this indication; if more inotropic effect is needed, epinephrine is probably a better choice than dopamine

because it is more potent, and dobutamine might be an alternative because it does not result in as much tachycardia as dopamine and has some afterload-reducing properties. In moderate to high doses, dopamine causes tachycardia (which increases myocardial oxygen demands), hypertension, arrhythmias, and, in some instances, extremity ischemia. At usual doses, dopamine should be given in a central vein, if possible; low doses (2–4 mcg/kg/min) may be given peripherally as long as careful monitoring of the extremity is undertaken to prevent infiltration and possible ischemic necrosis.

**DOBUTAMINE.** Dobutamine is a synthetic catecholamine with selective  $\beta_1$ -adrenergic action and a mild peripheral  $\beta_2$ -adrenergic effect (vasodilation), resulting in increased cardiac contractility, a mild increase in heart rate (but not as much as with dopamine), and decreased afterload (systemic resistance); this combination may significantly improve cardiac output. Dobutamine is most commonly used in patients with cardiogenic shock caused by myocarditis or cardiomyopathy or in children post-cardiac arrest. These patients usually have an adequate or excessive preload but have decreased contractility. Dobutamine provides improved contractility without as much tachycardia as is seen with dopamine or epinephrine. In children with a low preload, such as those with septic shock or anaphylaxis, the peripheral vasodilating effect of dobutamine may result in hypotension. Typical dosing starts at 2 to 5 mcg/kg/min and may be increased to 20 mcg/kg/min as tolerated. Dobutamine may be given peripherally because it has no significant vasoconstrictive effects.

**EPINEPHRINE.** Epinephrine is a catecholamine that is produced by the adrenal gland, but is also available for exogenous administration. It has dose-dependent effects— $\alpha$ -adrenergic (peripheral vasoconstrictive),  $\beta_1$ -adrenergic (inotropic, chronotropic, dromotropic), and  $\beta_2$ -adrenergic (vasodilatory). An epinephrine infusion is the treatment of choice for patients with marked circulatory instability and hypotension, given that it is potent and has superb inotropic effects and some vasoconstrictive effects in higher doses. The starting dose is 0.05 to 0.1 mcg/kg/min and may be increased up to 1 mcg/kg/min, with the dose titrated to reach the desired effect. In addition to its inotropic effect, lower doses under 0.1 mcg/kg/min usually result in peripheral vasodilation with a decrease in afterload. This circumstance may significantly improve cardiac output as long as preload is adequate. Higher infusion rates than 1 mcg/kg/min may be necessary in asystole. Epinephrine should be administered through a central line if at all possible, because at doses higher than approximately 0.1 mcg/kg/min, vasoconstrictive ( $\alpha$ -adrenergic) effects may be pronounced. The adverse effects of epinephrine infusion are tachycardia, arrhythmias, hypertension, hyperglycemia, and, at doses exceeding 0.5 mcg/kg/min, profound vasoconstriction that may compromise skin and extremity blood flow. Although epinephrine may reduce renal blood flow in high doses because of vasoconstriction, its inotropic effect improves renal blood flow by increasing cardiac output and tissue perfusion.

**NOREPINEPHRINE.** Norepinephrine, a catecholamine, is the neurotransmitter of the adrenergic nervous system and is noted primarily for its prominent vasoconstrictive ( $\alpha$ -adrenergic) effect, although it also has some moderate inotropic effect without the increase in heart rate so commonly seen with epinephrine. Infusion of norepinephrine is particularly useful in patients with shock in whom systemic vascular resistance needs to be increased rapidly (eg, warm septic shock, anaphylaxis, spinal shock). Infusions may be started at 0.1 mcg/kg/min and can be increased to 2 to 3 mcg/kg/min. Pronounced peripheral vasoconstriction may occur with a decrease in peripheral pulses and an increase in lactate, even though BP will be maintained. Its effect may be noted not only by an increase in BP, but also by an increase in diastolic BP, with a resulting narrow pulse pressure. Infusion should always be accomplished in a central line if at all possible because of its pronounced vasoconstrictive effects and significant risk of tissue ischemic necrosis, especially if it infiltrates.

**MILRINONE.** Milrinone is a phosphodiesterase inhibitor that has both inotropic effects, without an increase in heart rate, and vasodilator effects, resulting in afterload reduction. Over the last 10 years, experience with this class of drugs (which also includes inamrinone, an older drug of the same class) has been increasing for patients who have circulatory failure, especially from a primary cardiac etiology. Given milrinone's peripheral vasodilating effects, the patient should have sufficient preload (intravascular volume) so that hypotension does not result when it is started. The half-life of milrinone is also relatively long (4–6 hours); thus, its effects linger after it is stopped. For this reason, milrinone generally should not be used in the first few hours of stabilizing a patient, given that the physiologic state of the child may not be clear and may change quickly. Because no vasoconstrictive effects are associated with it, milrinone may be infused peripherally, aiming for a dose range of 0.25 to 0.75 mcg/kg/min. Although a loading dose should be considered for attaining rapid therapeutic blood levels, this amount may increase the risk of hypotension. Milrinone generally should not be considered as the drug of choice in forms of distributive shock, because a great deal of vasodilation is already present with low preload. However, in patients whose circulatory compromise is caused by cardiomyopathy, myocarditis, or poor cardiac function after cardiac arrest, this drug is excellent because it is not associated with the increased cardiac work caused by tachycardia. This drug has shown excellent results in pediatric patients who have undergone cardiopulmonary bypass for repair of a congenital heart defect and who have post-bypass circulatory compromise.

**SEPTIC SHOCK.** Septic shock contains elements of distributive, cardiogenic, and hypovolemic shock. Although infection with bacteria, viruses, and fungi is most commonly associated with septic shock, the constellation of signs, symptoms, and abnormalities in the physiologic mechanism of infectious septic shock may also be seen with noninfectious conditions (eg, severe hemorrhage, hypothermia). A cascade of cytokines and other inflammatory mediators are released, resulting in a systemic inflammatory

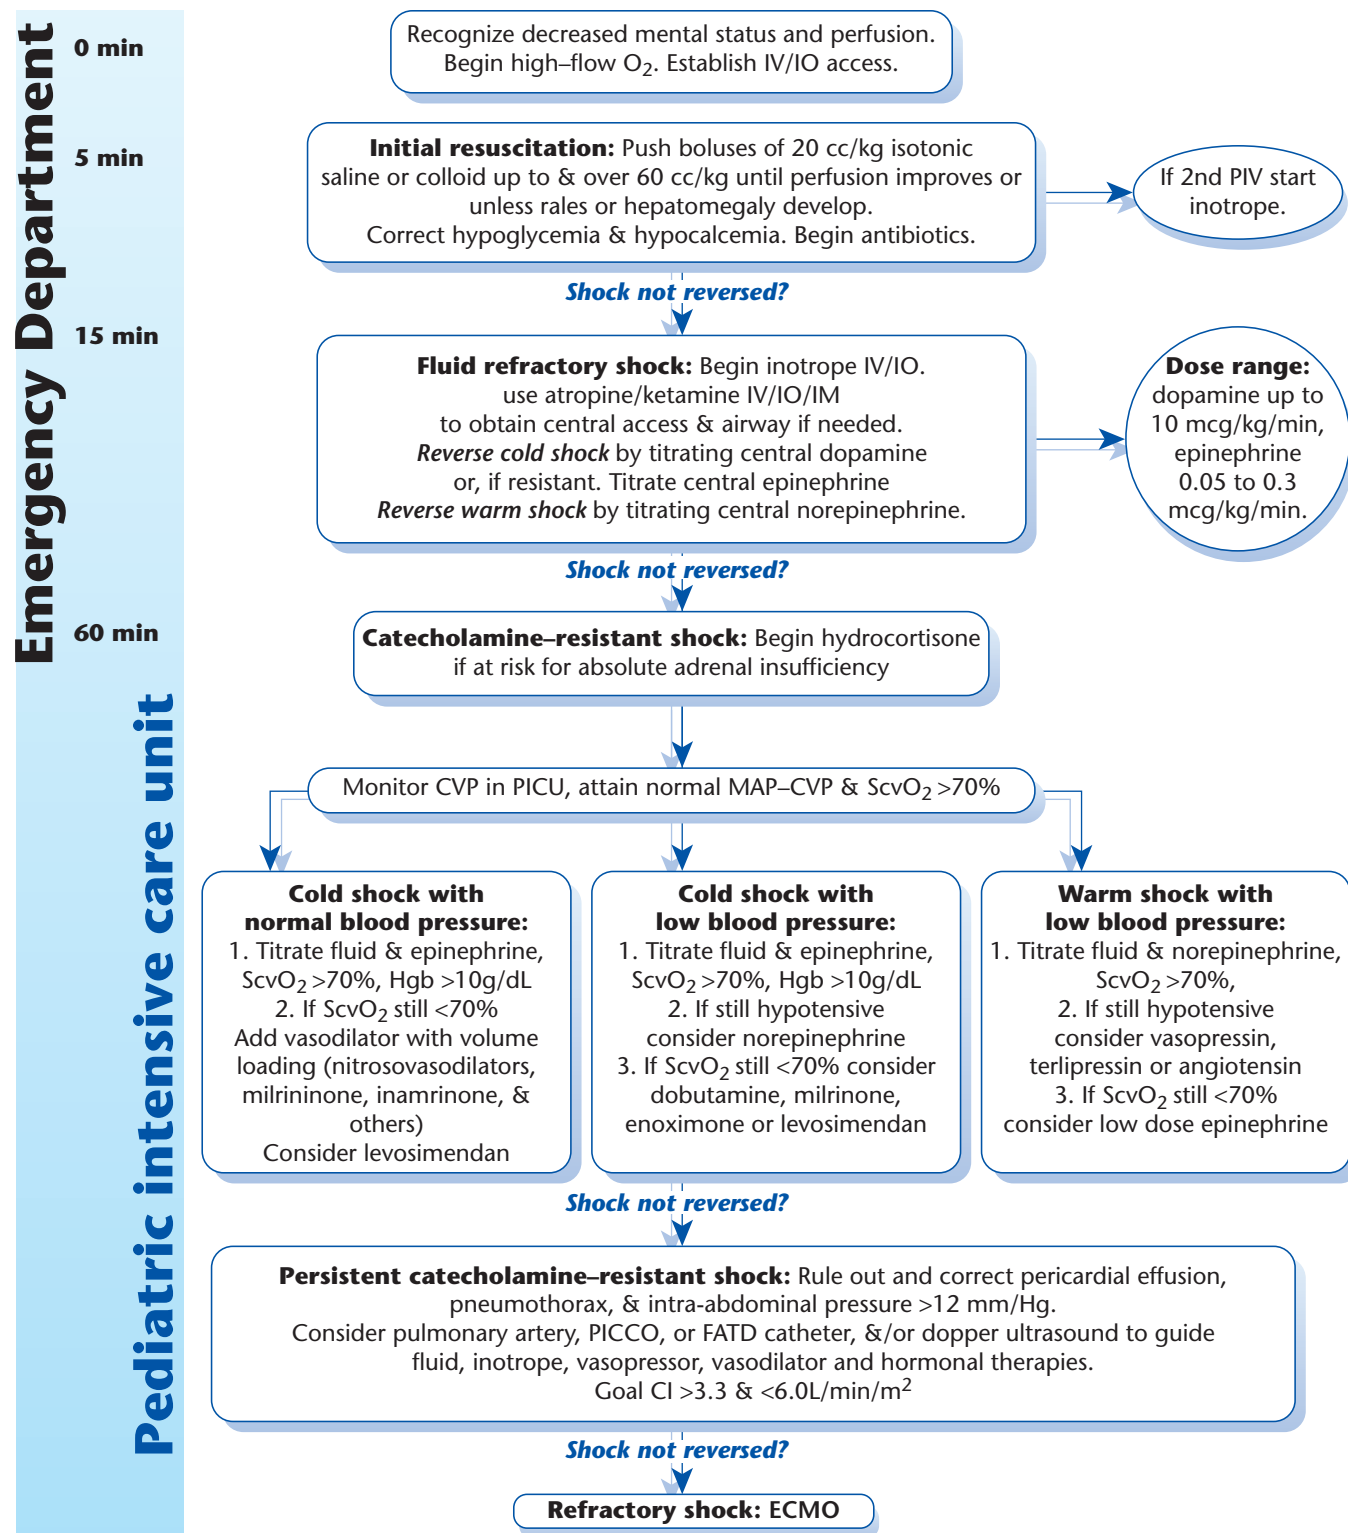

response syndrome (SIRS) reflected in metabolic, hemodynamic, respiratory, coagulation, and cellular disturbances. The result is a change in objective clinical and laboratory parameters, specifically temperature (fever or hypothermia), heart rate, respiratory rate, capillary refill, blood pressure, neurologic dysfunction, white blood cell count, coagulation tests, and both liver and renal function tests. If severe, this inflammatory response can lead to severe sepsis/septic shock.

With the recognition that rapid treatment of severe sepsis/septic shock is critical to improving survival, increasing attention has been given to defining sepsis and septic shock and developing guidance for their management. To this end, the international Surviving Sepsis campaign ([www.survivingsepsis.org/GUIDELINES/Pages/default.aspx](http://www.survivingsepsis.org/GUIDELINES/Pages/default.aspx)) has sought to promulgate management guidelines developed by a consensus of experts in the field.

A prominent feature of severe SIRS is that, in some patients, it can produce deceptively excellent perfusion with brisk (flash) capillary refill, bounding peripheral pulses, and pink, well-perfused skin (warm septic shock). Patients are usually febrile and may even have significant hypotension, but these are associated with excellent peripheral perfusion and a very high cardiac output. A major redistribution of blood occurs to the peripheral tissues, including skin and muscle, and low systemic vascular resistance results from the release of many cytokines. Nevertheless, although the patient initially seems quite well, the cardiac output is insufficient to meet the demands of the body, lactic acidosis occurs, and, over a brief period, peripheral vasoconstriction occurs with cool and poorly perfused extremities. Another complicating aspect of recognizing pediatric septic shock, and one that differentiates it from adult septic shock, is that BP may be normal and lactic acidosis may not be present.

Early recognition of septic shock is essential in improving morbidity and mortality. Very early and rapid fluid resuscitation seems to be key, with meticulous ongoing assessment to maintain cardiac output with both fluids and appropriate inotropic or vasoactive drug support. Because the adequacy of cardiac output can be deceiving, central venous oxygen saturation measurements can be helpful. These saturations reflect the adequacy of oxygen delivery to the tissues (determined by cardiac output, the amount of hemoglobin in the blood, oxygen saturation, and oxygen consumption by the tissues). Low central venous oxygen saturation (<70%) may indicate inadequate cardiac output and the need to improve it either by improving preload (intravascular volume) and cardiac contractility or by altering afterload. In addition, if the hematocrit is below 30%, transfusion of packed red cells should be considered to increase the oxygen-carrying capacity of the blood. Because relative adrenal insufficiency may also be present, steroids should be considered if response to fluids and vasoactive drugs is lacking. A full discussion of this complicated process is beyond the scope of this appendix, but an algorithm for the initial management of septic shock is shown in Figure A-4. See also Chapter 373, Shock.

**Figure A-4** Algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in infants and children. Proceed to next step if shock persists. (1) First-hour goals—Restore and maintain heart rate thresholds, capillary refill  $\leq 2$  sec, and normal blood pressure in the first hour/emergency department. Support oxygenation and ventilation as appropriate. (2) Subsequent intensive care unit goals—If shock is not reversed, intervene to restore and maintain normal perfusion pressure (mean arterial pressure [MAP]-central venous pressure [CVP]) for age, central venous O<sub>2</sub> saturation >70%, and CI >3.3, <6.0 L/min/m<sup>2</sup> in pediatric intensive care unit (PICU). CI, cardiac index; CRRT, continuous renal replacement therapy; ECMO, extracorporeal membrane oxygenation; FATD, femoral arterial thermodilution; Hgb, hemoglobin; IM, intramuscular; IO, intraosseous; IV, intravenous; PICCO, pulse contour cardiac output. (From Brierley J, et al. *Clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock: 2007 update from the American College of Critical Care Medicine*. ### Rhythm Disturbance Management

Although less common than in adult patients, cardiac rhythm disturbances in children are not rare and may result in significant morbidity and mortality. Given that bradycardias, tachycardias, and rhythms that result in no cardiac contractions (collapse rhythms) may also cause a significant drop in cardiac output, they should be recognized and managed expeditiously. Some arrhythmias occur suddenly without warning, with immediate cardiac compromise or arrest (eg, ventricular fibrillation, pulseless ventricular tachycardia); others occur more gradually secondary to hypoxia and metabolic problems. Some are associated with genetic syndromes (long QT syndrome, accessory tracts such as Wolff-Parkinson-White syndrome, channelopathies); others are the result of injury (*commotio cordis*), drug toxicity (beta-blocker overdose), congenital heart disease (including postoperative), or infectious etiologies (myocarditis).

Emergency management should be focused on initiating treatment only for rhythms that compromise cardiac output significantly or might deteriorate into a lethal rhythm. Emergency therapies include oxygen, medications, basic CPR (if indicated), and electrical therapy. Electrical therapy includes defibrillation, the delivery of a random (unsynchronized) electrical shock to the myocardium to eliminate all electrical activity (by depolarization) and allow for a return of sinus rhythm; and cardioversion, the delivery of an electrical shock synchronized with the ventricular R wave to stop rhythms generated from either atrial or ventricular ectopic foci and allow for the resumption of a sinus rhythm.

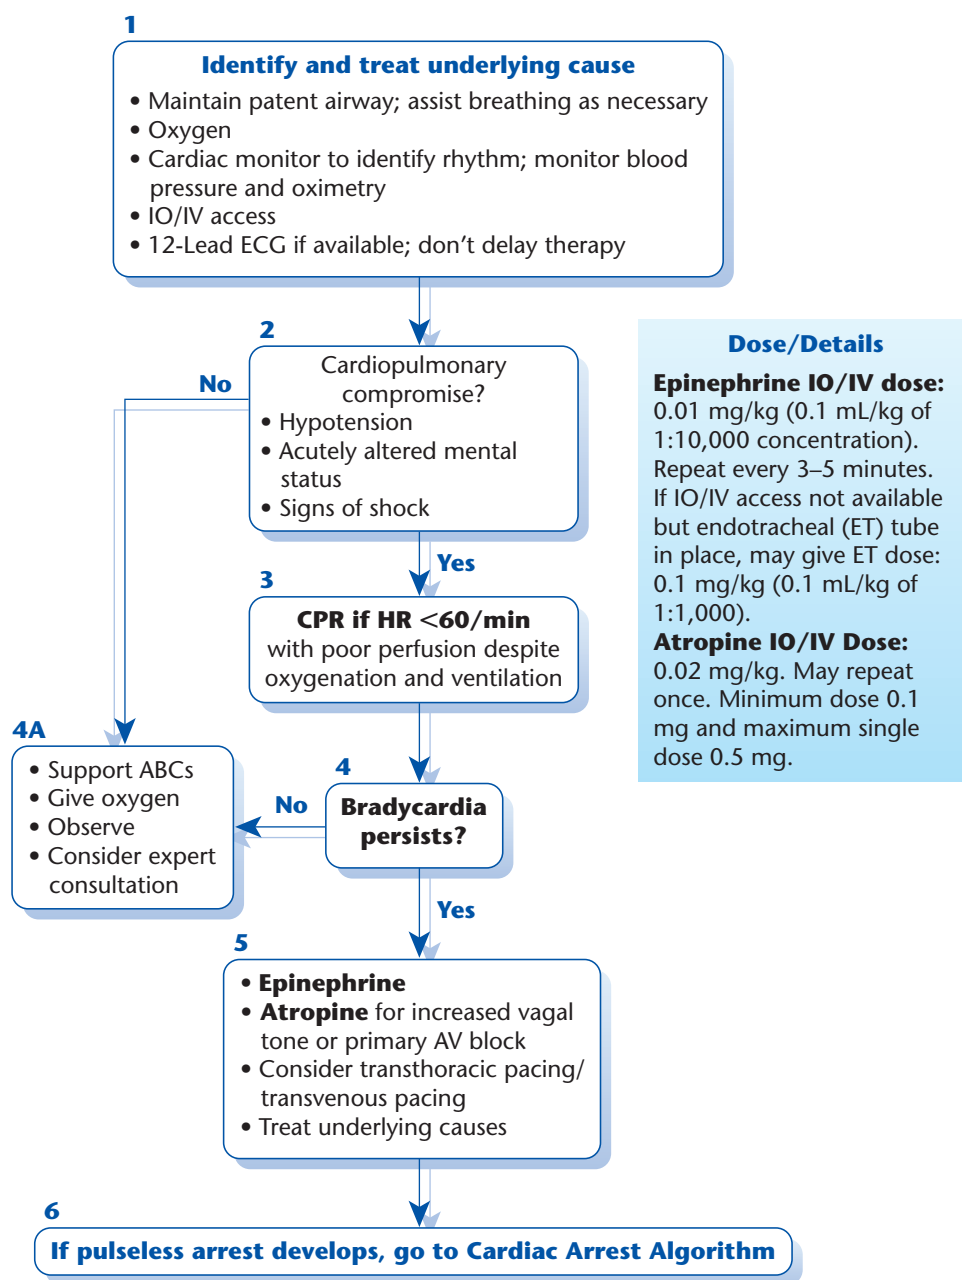

Appropriate therapies can be given only if at least some basic rhythm disturbances can be identified. Fortunately, a sophisticated knowledge of complex rhythms is unnecessary, and a noncardiologist can easily learn how to assess and provide the proper care for the common pediatric rhythm disturbances using the methods first described by the AHA in its first Pediatric Advanced Life Support Course in 1988 and continued in subsequent editions. This method, which divides rhythm disturbances into 3 major groups and uses group-specific algorithms for decision making, is outlined here. Other arrhythmias may need evaluation and treatment but do not usually constitute an emergency.

The 3 major rhythm groups are the bradycardias, the tachycardias, and the collapse rhythms. The last group includes any rhythm that does not have a discernible central pulse (ie, no recognizable cardiac output). Given that the grouping of the rhythms is

largely based on heart rate, knowing the ranges of normal in infants and children is important. In addition, a normal ECG must be recognized as consisting of a P-wave (atrial depolarization), followed by a QRS complex (ventricular depolarization and Q, R, and S waves), and then a T wave (reflecting ventricular repolarization). Table A-5 shows the normal ranges for heart rates and includes the normal PR and QRS complex intervals at various ages; although all of these values are important in interpretation of ECGs, the interval that is most important to assess is the length of the QRS complex. A QRS complex longer than 0.08 second in a child younger than 10 years (>0.10 second in the adolescent and adult) is consistent with one that originates in the ventricle (ventricular beat) or possibly originates from the atrium with some aberrant pathway. The length of this interval becomes important in differentiating an SVT from a ventricular tachycardia.

**BRADYARRHYTHMIAS.** Bradycardia below 60 bpm in infants and children is usually associated with poor perfusion (weak peripheral pulses, prolonged capillary refill, cool distal extremities with peripheral cyanosis) and requires emergency treatment even if the BP is normal. Figure A-5 shows the 2015 AHA recommended treatment algorithm. Given that hypoxia is a common cause of bradycardia, 100% oxygen should be given immediately and cardiac compressions instituted if bradycardia with poor perfusion continues. Because young children are especially dependent on their heart rate for maintaining cardiac output (they cannot increase stroke volume very readily), cardiac compressions at a rate between 100 and 120 compressions per minute begins to restore cardiac output immediately. Epinephrine in a dose of 0.01 mg/kg IV or IO should then be given, because epinephrine increases both heart rate and stroke volume. If no IV or IO access is possible and an ET tube is in place, epinephrine 0.1 mg/kg may be given as a 1:1,000 solution followed by 3 to 5 mL of normal saline and bagged in with 5 manual breaths.

Although epinephrine is generally the drug of choice in significant bradycardia, atropine may be considered first if excess vagal tone or atrioventricular (AV) block is present or if epinephrine is ineffective. Atropine competes with acetylcholine, the neurotransmitter of the parasympathetic nervous system, which includes the vagus nerve, thereby accelerating sinus and atrial pacemaker discharges and AV conduction. The dose of atropine is 0.02 mg/kg IV or IO (maximum of 0.5 mg). If no IV or IO line is in place and the child

**Figure A-5** Pediatric bradycardia with a pulse and poor perfusion algorithm. (From American Heart Association. Web-based integrated 2010 & 2015 guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Part 12: pediatric advanced life support. Reprinted with permission. © 2015 American Heart Association, Inc.)

is intubated, atropine in a dose 2 to 3 times the IV or IO dose can be given down the ET tube and followed by a normal saline flush. Atropine effects remain for 2 to 4 hours and may affect the pupillary response, making an accurate neurologic examination more difficult. However, a single dose of atropine is unlikely to result in full atropinization and elimination of pupillary responses.

If no response to these measures occurs, consideration should be given to increasing the heart rate by external pacing. Many defibrillator or monitor devices

now have multifunction pads for electrical therapy, allowing the same pads that are used for monitoring and defibrillation to be used for external pacing. Pacing should be initiated with 10 milliamperes (mA) and increased until a wide QRS complex follows the pacing spike (capture). Rate can be separately controlled and should start at 100. If the QRS complex occurs at 10 mA, the current can be decreased until it is at the lowest current that can generate a complex.

**TACHYARRHYTHMIAS.** By far, the most common cause of tachycardia in infants and children is a sinus

tachycardia induced by activity, fever, anemia, shock, and other reasons in which a need exists for increased cardiac output. In these patients, the primary problem is noncardiac, and the tachycardia is secondary and compensatory so that adequate cardiac output is maintained to serve the needs of the body. As the primary problem is treated (eg, fluids in hypovolemic shock, acetaminophen in a febrile child), the heart rate will decrease. However, in tachycardias that are truly dysrhythmic, tachycardia is the primary problem, often resulting in inadequate cardiac output and circulatory failure. If the heart rate is too rapid, filling time is inadequate, and thus the volume ejected with each beat is inadequate. Figure A-6 provides a treatment algorithm.

Tachycardias may be divided into those that originate from the supraventricular areas (atria, AV node) and those that originate from the ventricle. If the tachycardia originates from the ventricle, the QRS will be wide; if from above the ventricle, it will be narrow. A primary, intrinsic SVT should be considered if the heart rate in infants is over 220 bpm and in children is over 180 bpm. If any tachycardia is present and a wide QRS complex is observed, a ventricular tachycardia should be considered.

In SVT, P waves are difficult to find, the QRS complex is narrow in 98% of cases, and the rate is usually regular with an abrupt onset. If the patient is hemodynamically stable, vagal maneuvers may be tried (eg, applying an ice bag to the face suddenly, being careful to avoid obstructing the nose and mouth or having an older child exhale against an occluded straw). These maneuvers are often successful. If vagal maneuvers are unsuccessful, adenosine should be administered intravenously. Adenosine is an endogenous nucleoside that causes a temporary block through the AV node; it is very effective, and side effects are minimal because its half-life is only 10 seconds. However, because of its short half-life and the need to get the drug into the central circulation as soon as possible, adenosine in a dose of 0.1 mg/kg should be given by rapid IV or IO bolus immediately and followed by a 5- to 10-mL normal saline flush (this is usually a 2-person procedure using a 3-way stopcock). If unsuccessful, the dose may be doubled up to 12 mg (or even quadrupled if being given by IO infusion).

If the patient has significant hemodynamic instability and no IV line is in place to give adenosine rapidly, or if adenosine is unsuccessful, immediate *synchronized* cardioversion (0.5–1 J/kg) should be attempted. If SVT persists, the cardioversion dose should be increased to 2 J/kg. If it still persists, the diagnosis should be re-evaluated and a cardiologist consulted. Amiodarone at 5 mg/kg over 20 to 60 minutes should be considered. Verapamil should *not* be used to treat SVT in infants or children because cardiovascular collapse has been reported following its use in infants.

Ventricular tachycardia is characterized by wide QRS complexes, absence of P waves, and T waves that are opposite in polarity to the QRS complex. To be defined as ventricular tachycardia, at least 3 of these complexes in a row should be observed. Although patients may have sustained ventricular tachycardia for a short time without hemodynamic instability,

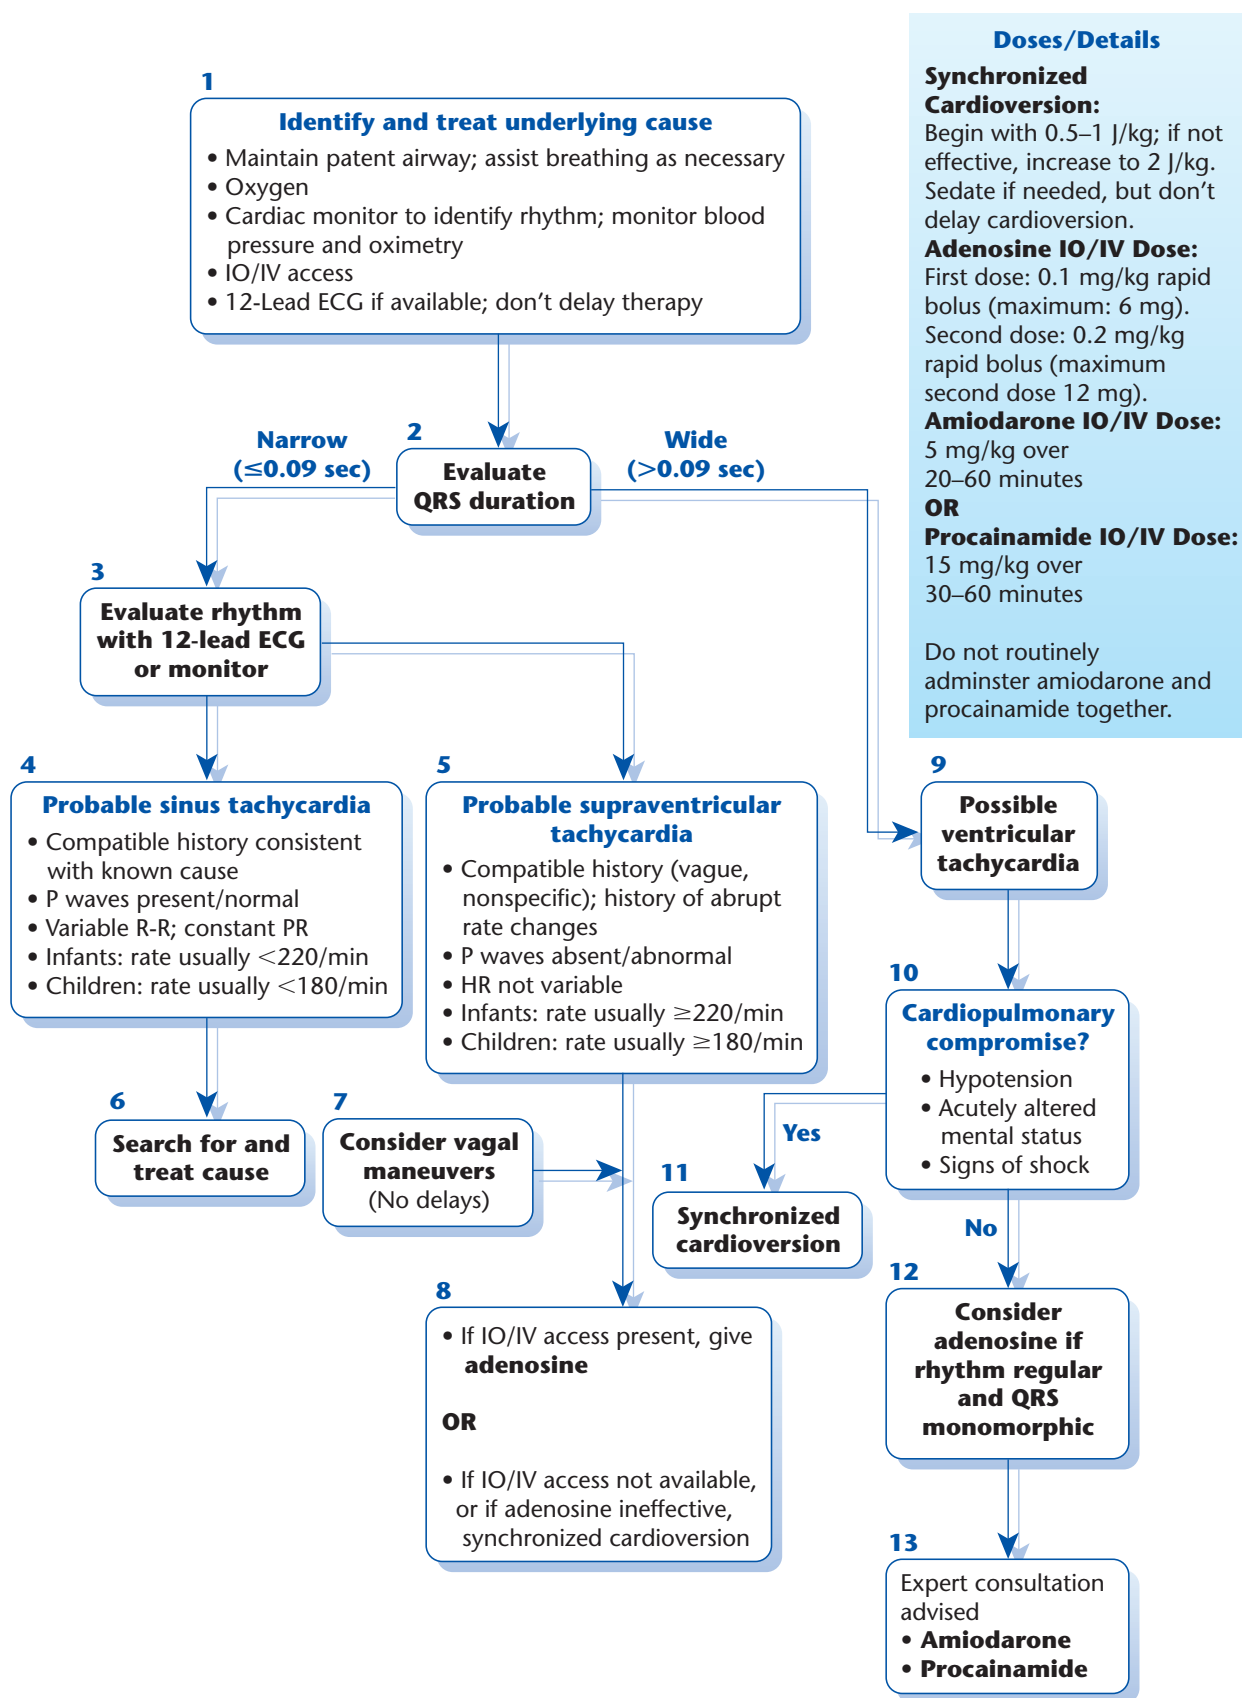

treatment should be instituted especially quickly because ventricular tachycardia with poor perfusion may rapidly degenerate into ventricular fibrillation.

If perfusion is poor, *synchronized* cardioversion (0.5–1 J/kg) should be attempted immediately. If it can be performed without delay, and if the rhythm is more likely to be aberrantly conducted supraventricular beats, adenosine may be given. Ventricular tachycardia will not be altered by adenosine. If no response to the first attempt at cardioversion is observed, the dose may be doubled (2 J/kg). If ventricular tachycardia recurs or no response to the second shock is observed, an infusion of amiodarone should be considered at 5 mg/kg IV or IO over 20 to 60 minutes (or 1 mg/kg every 10 minutes). A subsequent shock can be attempted once this circumstance has occurred. A pediatric cardiologist or pediatric intensive care physician (or both) should be consulted early in the management of ventricular tachycardia.

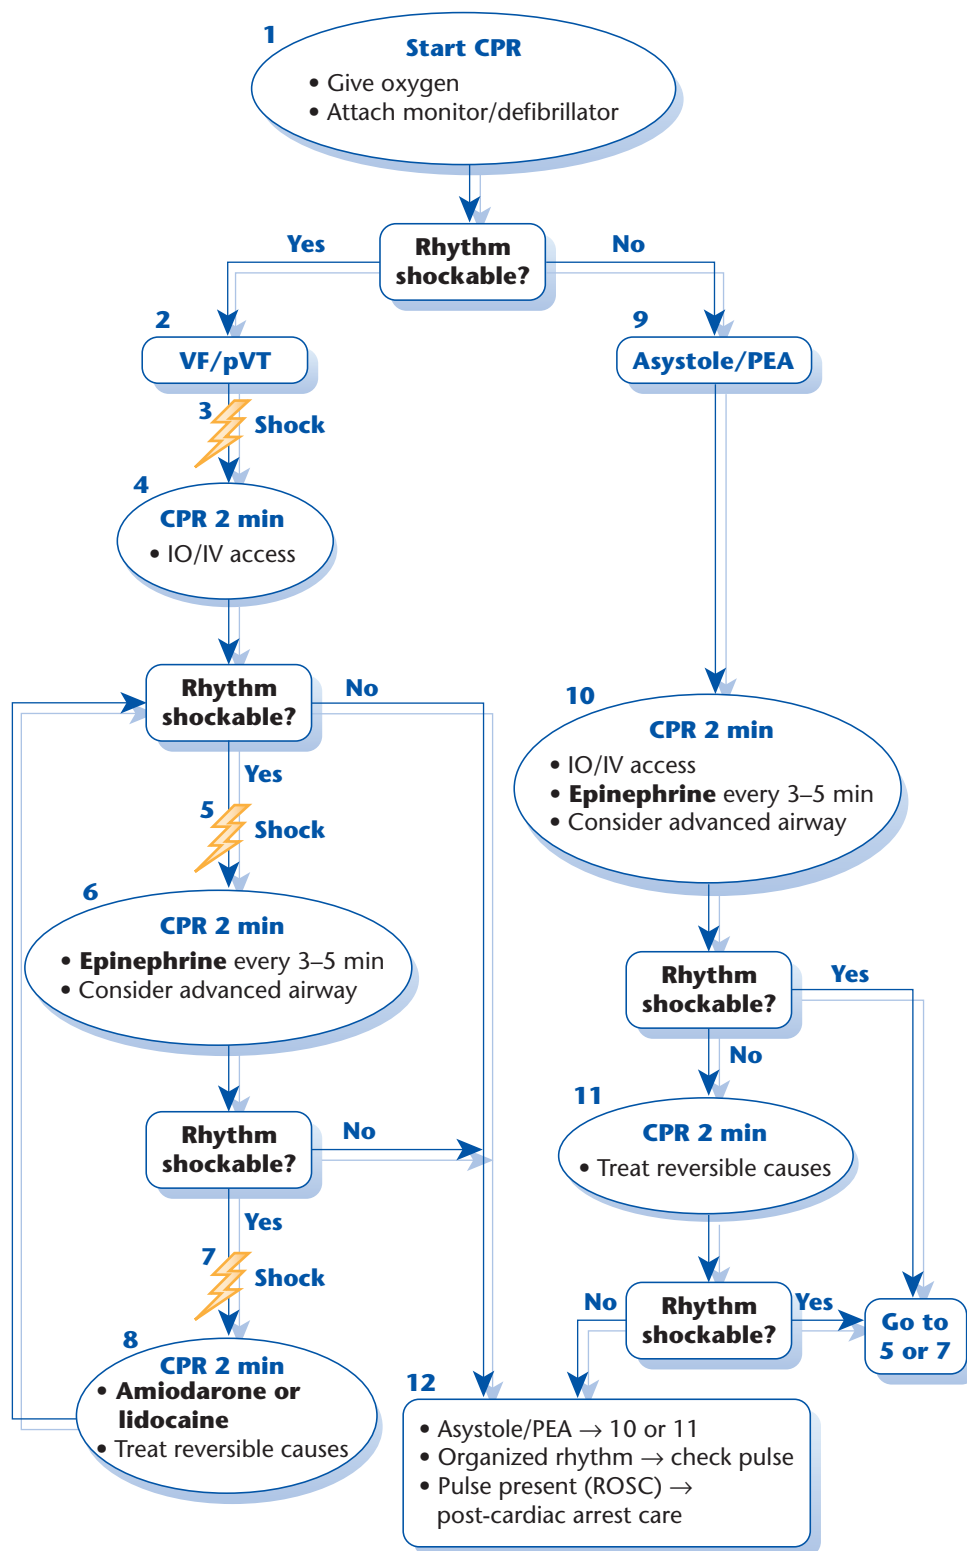

**COLLAPSE RHYTHMS OR CARDIAC ARREST.** None of the collapse rhythms—*asystole*, pulseless electrical activity, ventricular fibrillation, or pulseless ventricular tachycardia—produce sufficient cardiac output to generate a central pulse. Immediate basic CPR, as described previously, is necessary, with emphasis on chest compressions that are fast (at least 100 compressions/minute), have good compression depth (one-third to one-half the chest), and have complete recoil. Rapid connection of the patient to a monitor is imperative because the presence of ventricular fibrillation or ventricular tachycardia requires defibrillation as soon as possible, with best outcomes occurring if it is accomplished quickly (within 3 minutes). With each minute that passes, mortality increases by 10%. Figure A-7 provides a treatment algorithm for a pulseless arrest.

**ASYSTOLE AND PULSELESS ELECTRICAL ACTIVITY.** Asystole is the absence of any cardiac electrical activity and is characterized by the absence of any waveforms on the ECG. Pulseless electrical activity is any electrical activity, except for ventricular fibrillation and ventricular tachycardia, that has no central pulses associated with it. AHA Guidelines state the treatment of both is identical and consists of basic CPR, oxygenation, and the administration of epinephrine 0.01 mg/kg IV or IO (or 0.1 mg/kg by ET tube) every 3 to 5 minutes. CPR should be resumed immediately after epinephrine is given (to circulate the epinephrine and maintain coronary artery perfusion pressure) and continued for 2 minutes of CPR (5 cycles of 30:2 CPR for a single rescuer for the adult or 10 cycles of 15:2 CPR for 2 health rescuers for the child) before the rhythm is checked. If no response to this treatment is observed, possible reasons should be considered and treatment instituted. Considerations are outlined in Figure A-7 under 6 Hs (*hypovolemia*, *hypoxia*, *hydrogen ion*, *hyper- or hypokalemia*, *hypoglycemia*, and *hypothermia*) and 5 Ts (*toxins*, *tamponade-cardiac*, *tension pneumothorax*, *thrombosis-pulmonary or coronary*, and *trauma*). Many drugs that have been used in the past are no longer routinely recommended by AHA in pulseless arrest, especially intravascular or IO high-dose epinephrine (0.1 mg/kg), atropine, and calcium. High-dose epinephrine, in particular, is not recommended by AHA as a standard

## Doses/Details

### CPR Quality

- Push hard ( $\geq \frac{1}{3}$  of antero-posterior diameter of chest) and fast (100–120/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 minutes or sooner if fatigued
- If no advanced airway, 15:2 compression-ventilation ratio. If advanced airway, 8–10 breaths per minute with continuous chest compressions

### Shock Energy for Defibrillation

First shock 2 J/kg, second shock 4 J/kg, subsequent shocks  $\geq 4$  J/kg, maximum 10 J/kg or adult dose.

### Drug Therapy

#### • Epinephrine IO/IV Dose:

0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3–5 minutes. If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1,000 concentration).

#### • Amiodarone IO/IV Dose:

5 mg/kg bolus during cardiac arrest. May repeat up to 2 times for refractory VF/pulseless VT.

#### • Lidocaine IO/IV dose:

Initial: 1 mg/kg loading dose  
Maintenance: 20–50 mcg/kg per minute infusion (repeat bolus dose if infusion initiated >15 minutes after initial bolus therapy)

### Advanced Airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place give 1 breath every 6 seconds (10 breaths per minute) with continuous chest compressions

### Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Spontaneous arterial pressure waves with intra-arterial monitoring

### Reversible Causes

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypoglycemia
- Hypo-/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade, cardiac
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

medication in cardiac arrest because no consistent evidence has been found that it is effective and because some evidence suggests that it actually decreases survival, particularly in asphyxial arrest. High-dose epinephrine may be considered in special circumstances, such as beta-blocker overdose. Although sodium bicarbonate should not be used routinely, in prolonged arrest (more than 10 minutes) or with evidence of significant metabolic acidosis it may be used recognizing that it may result in an increase in intracellular acidosis. Recent evidence suggests that calcium is not appropriate unless there is documented or very high likelihood of hypocalcemia, hypermagnesemia, hypocalcemia, or calcium channel blocker overdose.

**VENTRICULAR FIBRILLATION OR PULSELESS VENTRICULAR TACHYCARDIA.** AHA guidelines recommend that defibrillation (unsynchronized shock) must occur as soon as possible, using appropriately sized pads or paddles (pediatric paddles are used for children weighing less than 10 kg), conducting gel as appropriate, and proper voltage (2 J/kg as a starting dose). Because most defibrillators are now biphasic with a success rate of 90% after 1 shock, AHA recommends only 1 shock. After the single shock, CPR is resumed immediately without checking the rhythm and continued for 2 full minutes. The reason for resuming CPR immediately is that, after defibrillation occurs, asystole or pulseless mechanical activity is usually present, both still requiring cardiac compressions. After the 2 minutes of CPR, the rhythm is rechecked, and if ventricular fibrillation or pulseless ventricular tachycardia is still present, a shock of 4 J/kg is delivered (compressions should be continued until the defibrillator is fully charged). CPR is resumed immediately and a dose of epinephrine (0.01 mg/kg up to 1 mg) is given via IV or IO line. After 2 minutes of CPR, another rhythm check is performed, and if ventricular fibrillation or ventricular tachycardia is still present, a 4 to 10 J/kg shock (up to the adult dose) is given with immediate resumption of CPR. Amiodarone at 5 mg/kg IV or IO push is then given. Alternately, lidocaine may be used if amiodarone is not available. Epinephrine is continued every 3 to 5 minutes, but AHA does not recommend vasopressin in children because no scientific evidence has been found to support its use in children, and only some mixed evidence in adults has been found. If no response occurs, the 6 Hs and 5 Ts should be reviewed to see if any other management is indicated (eg, a fluid bolus of 20 mL/kg to ensure adequate intravascular volume, checking blood glucose level to ensure the absence of hypoglycemia). If the rhythm suggests Torsades de pointes (a variant of ventricular tachycardia), magnesium at 25 to 50 mg/kg IV push should be given.

The sequence for managing ventricular fibrillation or pulseless ventricular tachycardia is very fast paced, requires thorough planning so that medications are given on time, and is dependent both on persistent, uninterrupted CPR and proper defibrillation. A team with assigned roles led by a capable team leader is invaluable in the rendering of optimal and timely management.

**CARDIAC ARREST MEDICATIONS.** Medications used in situations of cardiac arrest are listed and discussed in Table A-6.

**AMIODARONE.** Amiodarone is a class III antiarrhythmic that inhibits  $\alpha$ - and  $\beta$ -adrenergic receptors, slows the sinus rate, and prolongs the effective refractory period. In adults, it has been shown to be an excellent drug for the management of pulseless ventricular tachycardia and ventricular fibrillation at an IV or IO push dose of 5 mg/kg. In children, amiodarone is also useful in SVT and ventricular tachycardia with pulses. In the latter settings, 5 mg/kg IV or IO should be given over 20 to 60 minutes, thus over an appreciably longer time period than in the patient with cardiac arrest. Side effects include hypotension and prolongation of the PR and QT intervals. Although amiodarone has a fairly rapid onset of action (within 30 minutes), its terminal elimination half-life is extremely long (days to weeks). Caution should be used in neonates and young infants, because amiodarone preparations contain benzyl alcohol, which is associated with gasping syndrome and death in this age group.

**BICARBONATE (SODIUM).** Intravenous or IO administration of sodium bicarbonate (a base) can correct severe and ongoing metabolic acidosis. Although bicarbonate was previously used routinely during advanced CPR, some significant adverse effects should be considered. Bicarbonate shifts the oxygen dissociation curve to the left and thus reduces the delivery of oxygen to the tissues; shifts the potassium intracellularly, lowering its serum level and increasing the risk of arrhythmias; reduces plasma-ionized calcium and increases risk of arrhythmias; lowers the ventricular fibrillation threshold; increases the risk of hypernatremia and water overload; increases the risk of hyperosmolality with risk of cerebral bleeding; and may produce paradoxical cerebrospinal fluid and intracellular acidosis. Given these adverse effects, bicarbonate should be used cautiously and generally only if the acidemia is severe (pH <7.20) and not improving. Severe acidosis may depress cardiac contractility and result in poor cardiac output. Because the administration of bicarbonate increases  $P_{CO_2}$  by its combination with hydrogen ion ( $H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$ ), satisfactory ventilation must be established before administering it.

Because the acidemia that results from a metabolic acidosis can be corrected by inducing a respiratory alkalosis (decreased  $P_{CO_2}$ ), the following relationships, known as golden rules, are useful to know:

Rule 1: An acute change in  $P_{CO_2}$  of 10 torr is associated with an increase or decrease of 0.08 units in the pH.

Rule 2: A pH change of 0.15 units is associated with a change in bicarbonate of 10 mEq/L from its 20-mEq/L baseline.

Rule 3: The dose of bicarbonate (mEq) required to correct the metabolic acidosis *fully* is the base deficit (mEq/L  $\times$  patient's weight [kg]  $\times$  0.3). Usually, only one-half this amount is administered and then the acid-base status is reassessed. This amount translates into a bicarbonate dose of 1 mEq/kg.

Other indications for bicarbonate infusion include hyperkalemia and tricyclic antidepressant (sodium-channel blocker) overdose.

**Table A-6 Medications for Pediatric Resuscitation**

MEDICATION	DOSE	REMARKS
Adenosine	0.1 mg/kg (max: 6 mg) Second dose: 0.2 mg/kg (max: 12 mg)	Monitor ECG. Rapid IV or IO bolus with flush.
Amiodarone	5 mg/kg IV or IO; may repeat twice up to 15 mg/kg Max single dose: 300 mg	Monitor ECG and blood pressure; adjust administration rate to urgency (IV push during cardiac arrest, more slowly—over 20–60 minutes with perfusing rhythm). Expert consultation strongly recommended prior to use when patient has a perfusing rhythm. Use caution when administering with other drugs that prolong QT (obtain expert consultation).
Atropine	0.02 mg/kg IV or IO 0.04–0.06 mg/kg ET <sup>a</sup> Repeat once if needed Max single dose: 0.5 mg	Higher doses may be used with organophosphate poisoning.
Calcium chloride (10%)	20 mg/kg IV or IO (0.2 mL/kg) Max single dose: 2 g	Administer slowly.
Epinephrine	0.01 mg/kg (0.1 mL/kg 1:10,000) IV/IO 0.1 mg/kg (0.1 mL/kg 1:1,000) ET <sup>a</sup> Max dose: 1 mg IV/IO; 2.5 mg ET	May repeat every 3–5 minutes.
Glucose	0.5–1 g/kg IV or IO	Newborn: 5–10 mL/kg D <sub>10</sub> W Infants and Children: 2–4 mL/kg D <sub>25</sub> W Adolescents: 1–2 mL/kg D <sub>50</sub> W
Lidocaine	Bolus: 1 mg/kg IV or IO Infusion: 20–50 mcg/kg/min	
Magnesium sulfate	25–50 mg/kg IV or IO over 10–20 minutes, faster in torsades de pointes Max dose: 2 g	
Naloxone	Full reversal: <5 yr or ≤20 kg: 0.1 mg/kg IV, IO, or ET <sup>a</sup> ≥5 yr or >20 kg: 2 mg IV, IO, or ET <sup>a</sup>	Use lower dose to reverse respiratory depression associated with therapeutic opioid use (1–5 mcg/kg titrate to effect).
Procainamide	15 mg/kg IV or IO Adult dose: 20 mg/min IV infusion to total maximum dose of 17 mg/kg	Monitor ECG and blood pressure. Administer slowly—over 30–60 minutes. Use caution when administering with other drugs that prolong QT (obtain expert consultation).
Sodium bicarbonate	1 mEq/kg per dose IV or IO slowly	After adequate ventilation

BP, blood pressure; ECG, electrocardiogram; ET, endotracheal tube; IO, intraosseous; IV, intravenous.

<sup>a</sup>Flush with 5 mL of normal saline and follow with 5 ventilations.

From American Heart Association. *Web-based integrated 2010 & 2015 guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Part 12: pediatric advanced life support.* Reprinted with permission. © 2015 American Heart Association, Inc.

Given that the osmolality of the standard sodium bicarbonate preparation is very high (1 mEq/mL, 8.4%) and neonates, especially premature ones, are at risk for having central nervous system bleeding when high osmolar substances are infused, they should receive more dilute bicarbonate at a concentration of 0.5 mEq/mL (4.2%).

#### **CALCIUM CHLORIDE OR CALCIUM GLUCONATE.**

Calcium has a positive inotropic effect on the heart, but calcium entry into cell cytoplasm is also the final common pathway in cell death. These 2 paradoxical effects require judicious use of calcium, and its use is no longer routinely recommended in cardiac arrest protocols. Nevertheless, indications do exist for calcium administration—documented hypocalcemia,

hyperkalemia, hypermagnesemia, and calcium-channel blocker overdose. Calcium chloride is the salt preferred in emergency hypocalcemia because it delivers ionized calcium directly into the bloodstream. It should be given centrally if at all possible because it may cause severe arterial vasoconstriction, even when no discernible infiltrate is present. Calcium gluconate is better tolerated peripherally, but it requires first-pass metabolism in the liver before calcium ion is released. The dose of calcium gluconate (60 mg/kg) is 3 times the dose used for calcium chloride (20 mg/kg). Calcium should always be injected slowly, concurrent with ECG and BP monitoring, because bradycardia and hypotension may occur.

**EPINEPHRINE.** (See previous discussion under Circulatory Management.) Epinephrine is an endogenous catecholamine that can affect the adrenergic nervous system by stimulating  $\alpha$ -adrenergic (vasoconstricting),  $\beta_1$ -adrenergic (cardiac), and  $\beta_2$ -adrenergic (vasodilating) receptors. In doses used for CPR (0.01 mg/kg IV or IO), it has predominantly strong  $\alpha$ -adrenergic effects.  $\alpha$ -Receptor stimulation results in vasoconstriction, thereby increasing systemic vascular resistance, increased coronary artery perfusion pressure, and increased oxygen delivery to the myocardium. Because of this effect, epinephrine is indicated in asystole, pulseless electrical activity, pulseless ventricular tachycardia, and ventricular fibrillation. Epinephrine's  $\beta$ -adrenergic effects result in increased cardiac inotropy, (increased contractility), chronotropy (increased rate), and dromotropy (increased intracardiac conduction). These effects are very useful in managing unstable bradyarrhythmias, hypotensive shock, and anaphylaxis, and during the postresuscitation phase when the heart needs assistance in contractility and stroke volume. High-dose epinephrine (0.1 mg/kg) should be given only down the ET tube during cardiac arrest when no other means is possible to give standard dose epinephrine (0.01 mg/kg) or IV when beta-blocker overdose has occurred with an inability to increase the heart rate.

**GLUCOSE.** Small infants and chronically ill children have limited glycogen stores, and hypoglycemia may develop quickly. Glucose is a major metabolic substrate for the neonatal myocardium. A rapid blood glucose test should be obtained, and if hypoglycemia exists, glucose should be administered. In children older than 1 month, dextrose as a D<sub>25</sub>W solution (dilution of D<sub>50</sub>W 1:1 with sterile water) should be used in a dose of 2 to 4 mL/kg. In infants younger than 1 month, a D<sub>10</sub>W solution (dilution of D<sub>50</sub>W 1:4 with sterile water) in a dose of 8 to 10 mL/kg is preferred. In the older child, the usual adult dose of D<sub>50</sub>W solution at 1 to 2 mL/kg up to 50 mL (25 g) is given. Sufficient amounts should be given to keep the blood glucose level above 100 mg/dL. The diluted dextrose is important because repeated hyperosmolar doses have been associated with intracranial hemorrhage in premature infants.

**LIDOCAINE.** Lidocaine is a class IB antiarrhythmic and, in usual doses, has no effect on myocardial contractility, BP, or cardiac conduction. Its action reduces ventricular automaticity, raises the ventricular fibrillation threshold, and inhibits the formation of re-entry circuits that lead to ventricular tachycardia and ventricular fibrillation. It may be considered as an alternative to amiodarone.

To ensure adequate plasma concentrations, a bolus of 1 mg/kg should be given. If the child is in shock or has liver disease, beginning doses of 1 mg/kg/hr (15–20 mcg/kg/min) should be used to prevent toxicity from impaired lidocaine clearance. The dose for an adolescent is a 50- to 100-mg bolus followed by infusion of 1 to 4 mg/min. The antiarrhythmic effect occurs at a serum concentration of 1 to 5 mcg/mL. Concentrations above 6 mcg/mL may cause seizures, and those above 10 mcg/mL may cause myocardial depression. The physician should be prepared to treat bradycardia and hypotension. Lidocaine is

contraindicated in severe heart block and should not be given in idioventricular rhythms. Widening of the QRS complex by more than 0.02 seconds or significant ventricular slowing suggests cardiac toxicity.

Procainamide can be used for ventricular tachycardia with pulses or atrial flutter as long as there is a pulse, but it generally should NOT be used for ventricular fibrillation or ventricular tachycardia without pulses. It is a negative inotrope and can result in significant hypotension as well as prolongation of the QT interval. It should be used only with expert consultation. Concomitant use with amiodarone should be avoided.

## POSTRESUSCITATION MANAGEMENT

Once initial, urgent therapies have been provided for the critically ill infant or child, further stabilization, a method for performing frequent assessments, and a plan for safe and efficient transfer to a place where definitive care can be rendered need to be addressed. Early consultation with a pediatric tertiary care center is strongly recommended, especially if the infant or child is in a facility without pediatric tertiary care expertise. Ongoing close monitoring and treatment are imperative, because rapid deterioration may again occur unless proper care is rendered. For children who have had a respiratory or cardiac arrest, such definitive care involves transfer to a pediatric intensive care unit where multidisciplinary pediatric critical care expertise is available.

### Important Considerations

#### Monitoring

Ongoing cardiopulmonary monitoring with frequent nurse/physician assessments of the patient are imperative after a cardiopulmonary arrest so that early interventions can be made as necessary.

**RESPIRATORY ASSESSMENTS.** Respiratory assessments should include adequacy of airway; respiratory rate, depth, and effort; and pulse oximetry. An arterial blood gas assessment should be obtained if any questions exist about adequacy of ventilation or oxygenation. Results can then be correlated with the clinical examination. In addition to pulse oximetry, capnography (end-tidal Pco<sub>2</sub>) should be encouraged for intubated patients, and is recommended if they are to be transported within or to another facility.

**CARDIOVASCULAR ASSESSMENTS.** Cardiovascular assessments should include heart rate, continuous ECG, BP assessment by either frequent cuff pressures or arterial line, peripheral and central pulses, capillary refill, and urine output. Placing the child on a continuous ECG or respiratory monitor is most efficient, with noninvasive BP readings taken at regular intervals. If the child has unstable BPs, an arterial line should be inserted as soon as possible. A bladder catheter should be placed for ongoing monitoring of urine production (adequate urine output suggests adequate perfusion to the kidneys). Although usually not feasible in the initial stages of treatment, central venous pressure monitoring should be considered early on because it can be very helpful in monitoring the adequacy of preload. In addition, by having a central line in place, blood samples can be drawn from the central circulation to measure systemic

venous oxygen saturations ( $SvO_2$ ), and medications that require central vein infusion can be given as necessary. Desirable central venous oxygen saturations are at or above 70%. If these values are below this level in the setting of normal arterial oxygen saturations, the cardiac output may be insufficient and need to be corrected.

**NEUROLOGIC ASSESSMENTS.** Neurologic examinations should be performed frequently and include level of consciousness (use the AVPU scale or the Glasgow Coma Scale to assess responsiveness), pupillary responses, any evidence of increased intracranial pressure (decreased responsiveness, nonreactive or unequal pupils, abnormal respirations including hyperventilation and irregular respiration, Cushing's triad of bradycardia, hypertension and abnormal breathing), and seizures. Seizures occur frequently after cardiac arrest. This evaluation is especially important for patients who, in addition to the cardiac arrest, have also sustained a head injury, have a primary neurologic problem such as status epilepticus or meningitis, or have significant elevations in  $PCO_2$  or significant hypoxia.

**TRAINED PERSONNEL.** Although technical monitoring is necessary, staff trained to perform acceptable physical assessments and interpret data from monitors are essential. Early deterioration in a patient may be subtle, and an experienced health care provider can often note this event. Critically ill or injured patients who are not yet stabilized should never be left alone to depend exclusively on mechanical monitors.

### General Management

**RESPIRATORY.** The child should receive 100% oxygen (preferably humidified and at body temperature) until lower levels are clearly acceptable with maintenance of oxygen saturation in the 95% to 99% range. Careful attention to the level of oxygenation is especially important for patients who have had a cardiac arrest, because excess oxygen may result in the generation of injurious free oxygen radicals in brain tissue. Although the optimal oxygen level post arrest is not known, keeping oxygen at physiologic  $PO_2$  levels of 90 to 100 ( $O_2$  saturation 94%–99%) is recommended by the AHA. If the child has not had a cardiopulmonary arrest, but concerns exist about her ability to maintain adequate oxygenation and ventilation during transport to definitive care, the child should be intubated and placed on mechanical ventilation. A chest radiograph should be obtained to ensure that the ET tube is in the right position (midtrachea), and the tube should be well secured with tape. Initial settings for the ventilators are as follows:  $F_{IO_2}$ , 1.00; positive end-expiratory pressure (PEEP), 5; pressure support, 8 (if available); tidal volume, 8 to 10 mL/kg; peak inspiratory pressure (inspiratory + PEEP), 20 to 30 cm  $H_2O$ ; inspiratory time, 0.5 second for infants and 1 second for older patients, and a rate of approximately 20 inspirations per minute. There should be a discernible, but not excessive, chest rise with each breath. Further adjustments should be made based on arterial blood gas levels. A nasogastric or orogastric tube should be placed after intubation so that gastric air can be removed intermittently manually or by low intermittent suction.

**CARDIOVASCULAR.** Thorough assessment and ongoing management of preload (intravascular volume), contractility, and afterload is necessary in every critically ill child because rapid deterioration may occur again. This effort requires the placement of at least 2 well-secured functional venous lines. If fluid boluses are required, they should be given in 20 mL/kg aliquots over approximately 10 minutes. Assessment of heart rate and pulses during and after a bolus (rate should decrease, pulses increase) will provide immediate feedback regarding the appropriateness of this therapy. If blood is required (eg, in trauma patients), it should be given in 10 mL/kg of packed red blood cells. Inotropic support may also be necessary.

Once adequate preload has been established and the child or infant needs inotropic support, dopamine or dobutamine can be used for the child with nonhypotensive shock, and epinephrine or norepinephrine for children who are hypotensive. For the child who has had a cardiac arrest, improving contractility without excessive tachycardia is important, because the latter results in significantly increased oxygen requirement. Because dobutamine will typically result in less tachycardia than dopamine, it might be a better drug to use post arrest. Although milrinone or amrinone are excellent drugs to use after a child has had cardiac arrest (neither results in tachycardia, but both have inotropic and afterload-reducing effects), they may require the expertise of a pediatric critical care physician.

**NEUROLOGIC.** Hyperventilation, hyperglycemia, hypoglycemia, and fever should all be avoided because they may result in less-than-optimal outcomes. Unless used for acute rescue (signs of impending cerebral herniation), hyperventilation has no benefit and may significantly impair neurologic outcomes. Hyperventilation results in a drop of  $PCO_2$  with resultant cerebral artery vasoconstriction and ischemia, especially in specific areas in which circulatory compromise has occurred. In addition, each time a breath is given, cardiac output is jeopardized (positive-pressure breath decreases venous return and subsequent cardiac output), including cerebral blood flow.

Hyperglycemia has been associated with unfavorable neurologic outcomes in adult patients with stroke and an increase in mortality for adults with critical illness. Maintaining good glycemic control in critically ill medical and surgical adult patients has been demonstrated to improve morbidity and mortality. There are no published studies in children, but it may be that hyperglycemia is also not useful in pediatric patients. However, hypoglycemia is a significant risk factor in young children particularly and should be prevented. Thus, glycemic control is becoming more important in the management of critically ill patients, and the patient is probably served best by maintaining normoglycemia.

Fever results in increased metabolic activity of the brain with worse outcomes noted post-cardiac arrest in both animals and humans. For this reason, fever should be assiduously prevented. Based on an international, prospective, randomized pediatric study (Therapeutic Hypothermia After Pediatric Cardiac Arrest—THAPCA study), the 2015 AHA Resuscitation Guidelines

recommend continuous temperature measurement for the first 5 days after arrest with goal temperature either normothermic (36–37.5° C) for these 5 days, or a combination of 2 days of mild hypothermia (32–34° C) followed by 3 days of normothermia. Similar targeted temperature strategies have also been recommended for adults with aggressive assessment and control of any fever.

Postischemic and recurrent seizures secondary to metabolic abnormalities (hypoglycemia or hypocalcemia) may occur and should be treated aggressively. IV lorazepam (0.05–0.1 mg/kg) is often effective and may be followed by IV phenytoin (20 mg/kg) (or fosphenytoin in young patients or in patients with cardiovascular instability) for additional control. Children who have had an intracranial bleed may be at higher risk for seizures and are often treated with phenytoin prophylactically. Although it may not be possible to fully implement these therapies until the child is admitted to the pediatric critical care unit, they often need to be initiated while arrangements are being made for transport to such a facility.

**RENAL.** The goal for urine output should be between 1 and 2 mL/kg/hr. Because the adequacy of urine output is an indirect measurement of the adequacy of cardiac output, a bladder catheter is recommended whenever concern exists about a child's hemodynamic state. Low urine output may require an adjustment of preload by infusing a fluid bolus or an adjustment of vasoactive drugs to improve cardiac contractility. It is essential to use the urine output in conjunction with other assessments of the cardiovascular system, such as heart rate, pulses, BP, and capillary refill, because urine output may be low for other reasons.

**INFECTIOUS.** After providing the initial management of a critically ill patient, including the patient who has suffered a respiratory or cardiac arrest, early treatment for suspected infectious disease should occur. After suitable cultures are taken (usually at least a blood and urine culture), broad-spectrum antibiotics should be started to cover the most likely causes. Ceftriaxone at 50 mg/kg IV or intramuscularly for possible sepsis or 100 mg/kg for possible meningitis is an excellent choice for patients who are older than 6 weeks; for those younger than 6 weeks, ampicillin plus gentamicin or cefotaxime should be used so that infections from the perinatal period are covered. If herpes encephalitis is a possibility, acyclovir should also be started.

If bacterial sepsis is present and antibiotics are given, significant hemodynamic instability may occur within an hour of antibiotic administration. As bacteria die, a significant release of inflammatory mediators will occur, resulting in vasodilation, an increase in capillary permeability, third-spacing, depression of myocardial function, and concomitant hypotension. Additional boluses of fluid may be required to maintain preload, and continuous monitoring of hemodynamics is essential, particularly if the patient is to be transported to another facility.

**HEMATOLOGIC.** As part of the initial assessment (tertiary assessment), it is important to make sure that the child has a sufficient number of red blood cells to transport oxygen and a sufficient number of white blood cells to fight infection. Severe anemia may significantly interfere with oxygen carrying capacity

and require correction. Moreover, ongoing blood losses may occur that are occult, particularly in trauma victims. Additional laboratory studies that should be obtained in addition to hematocrit and hemoglobin include platelets, prothrombin time, partial thromboplastin time, and international normalized ratio. Coagulation disturbances are extremely common in critically ill patients and may require early correction if the child is bleeding. It is best to discuss the need for correction of these parameters with a tertiary care center before providing therapy, because transfusions themselves may result in complications.

**METABOLIC.** In the postresuscitation phase of a critically ill child or a child who has had a cardiac arrest, several minerals require correction to optimize cardiac function. These minerals include calcium, potassium, phosphate, and magnesium. Restoration of all 4 of these ions to normal levels will allow for best cardiac muscle function and reduce the likelihood of an arrhythmia mediated by a deficiency in one of these minerals. If replacement is necessary, infusion over an hour is the norm, with continuous ECG monitoring for any arrhythmias and concomitant frequent BP checks. Severe acidosis (pH <7.20–7.25; base deficit of –6 or more), especially in a recently arrested patient, should probably be corrected by the administration of sodium bicarbonate at 1 mEq/kg. Hyperglycemia should also be prevented, with blood glucose levels kept below 150 mg/dL. Hyperglycemia may result in glycosuria with an osmotic diuresis and a decrease in intravascular volume or preload with subsequent worsening of cardiac output.

### Interfacility Transport

Agreements, protocols for specific clinical situations, and general protocols for transport to the regional pediatric tertiary or quaternary care center should be prepared in advance by key stakeholders. Input from primary care physicians (pediatricians, family practitioners), community hospitals or emergency rooms, regional pediatric hospitals (especially pediatric emergency medicine and critical care physicians), out-of-hospital emergency medical service providers, and insurance companies is crucial to this effort. Developing a general system of pediatric emergency transport in an area helps ensure that children will likely reach definitive care faster and more safely, and will receive the best care possible. In planning such a system, consideration should be given to the types of expertise (physicians, nurses, laboratory, radiology, inpatient beds) present in each local facility or region, the geography (including terrain, weather factors, and distance from regional pediatric centers), the availability and expertise of out-of-hospital or pre-hospital care providers, the transport modes available (ground vs air), and the mechanisms necessary for effective and efficient communication. An important point to note is that the sending facility is responsible for ensuring that both the transport and the facility to whom the child is transported are appropriate.

Even though a general system of pediatric transport care may be in place, each pediatric patient who requires transfer should be assessed thoroughly to

determine the child's specific needs. Decisions must be made regarding the speed of transport to a pediatric tertiary care facility, the makeup of the team that is to transport the child, the need for a pediatric specialty transport team, and the mode of transport (air vs ground; weather considerations). The expertise and comfort level of the providers who gave initial care should also be assessed along with their ability to provide care in the interim until the transport team takes over. Because of the complexity of these decisions, a pediatric transport expert from the regional center must be consulted to give recommendations about the preparation and method of transport. In many regional pediatric centers, formal pediatric transport programs are in place to assist in this transfer process, with experienced teams led by trained pediatric transport nurses overseeing the transports and coordinating the process under the supervision of pediatric intensivists or pediatric emergency medicine physicians.

To ensure that decisions about the transport can be made as easily as possible, the referring physician should provide the following information to the consulting or receiving facility:

1. The referring hospital's name and location and the referring physician's name and telephone number
2. The child's name, age, and weight and the parents' names, address, telephone number, and insurance carrier
3. A history of the present illness and significant elements of the past history, including medications and any allergies
4. The current clinical status, including the level of consciousness, heart rate, presence and adequacy of peripheral pulses, capillary refill time, respiratory rate, air entry status, respiratory effort, skin color, body temperature, and BP
5. Results of diagnostic tests—laboratory, radiologic, ECG or echocardiographic; copies should be made of radiographs so that the receiving hospital can re-review, or the radiographs should be made electronically available
6. All medications and fluids administered, including dosages and times given
7. Number of IV or IO and central lines, including their infusion rates
8. Size of ET tube, cuffed or uncuffed, tip location on chest radiograph, and ventilator settings
9. Availability and condition of parents or primary care physician for providing consent for treatment

If a pediatric specialty team is unavailable for the transport, arrangements must be made to manage any problems that might occur during the transport, including clearly defining the person or persons who will be responsible, particularly which physician is accepting responsibility.

Communication should occur at multiple levels during the transport process. In addition to communication between referring and receiving physicians, communication should be established among nursing staff at both institutions, social workers (when available), and administrative personnel to deal with such factors as insurance and the admission process.

The Section on Transport Medicine of the AAP has published comprehensive guidelines for air and ground transport of critically ill pediatric patients.

## FINAL CONSIDERATIONS

### Family Presence During Resuscitation

It has become increasingly common for families to be present during pediatric resuscitation and invasive procedures. Families who have been present during a resuscitation have usually expressed how much it meant to them to be near to their loved one, even when the child did not survive, and how much they appreciated what the resuscitation team was trying to do. Although having the family present during such a stressful time may be difficult for some caregivers, it is now recognized that there is significant value to this presence. However, because many aspects of care might be confusing and frightening to the family during the resuscitation, a person must be designated to attend to the family and be able to explain what is happening.

Similarly, it is now recognized that not only is the family presence important during a resuscitation of a child, but there are many peri-resuscitation issues that need to be addressed. Appropriate communication with the family both during and after the resuscitation is critically important. Discussion of organ donation, autopsy, medicolegal issues, and appropriate follow-up with the child's primary care physician and/or specialists who have been involved with the care previously are all important. It is best that written protocols are established so that none of these aspects of care around the time of resuscitation are missed. The AAP, along with the American College of Emergency Physicians and the Emergency Nurses Association, have developed a policy statement that addresses many of these issues.

### Brain Death and Organ Donation

With aggressive attention to identifying children who are at risk for developing respiratory or cardiac arrest, instituting management to prevent further deterioration, and optimizing respiratory and cardiac arrest management when they do occur, the hope is that outcomes are better. Nevertheless, children continue to experience cardiac arrest with severe neurologic morbidity and mortality. Unfortunately, predicting accurately during a resuscitation which children will ultimately not survive and when to terminate resuscitation efforts is impossible. Longer efforts should probably be made for children who have primary hypothermia (eg, falling into freezing water) and who have ventricular fibrillation with rapid bystander CPR and quick defibrillation.

One of the most difficult situations after a cardiac arrest is when a child who is resuscitated from the initial cardiac arrest progresses to brain death over the next 24 to 48 hours. This is the time when great expertise is needed to help the family understand the concepts of brain death and its implications. Formal and strict criteria have been developed for pediatric patients and should be meticulously applied. Moreover, because many families would like to donate the

child's organs, a thorough and complete brain death assessment should be performed by the medical team while professional certified organ procurement staff (as determined by the US Code of Federal Regulations, 42 CFR 482.45 governing organ, tissue, and eye procurement) assist in ensuring the best donating outcomes for the family once brain death has been determined (the time of brain death is the same as the time of pronouncing the child dead).

In the event that the child cannot be declared brain dead, donation of organs may still be accomplished by removing the organs immediately (within minutes of cardiac death in the operating room) after withdrawing support in a hopeless situation. This type of patient is classified as *donation after cardiac death* (DCD), and specific protocols should be available for this method of donating organs. Although initially done primarily in adult patients who died, this is now increasingly common in pediatrics where families wish to have some good come out of their child's death.

### Do-Not-Resuscitate Orders

The purpose of basic and advanced life support is to prevent sudden, unexpected, and unwanted death. However, these therapies may not be indicated when a child has a terminal, irreversible illness in which death is not unexpected, when resuscitation is likely to result in a poor neurologic outcome, or when these efforts are likely to be futile. Whenever a decision to forego CPR is made after thorough discussion with the family, a do-not-resuscitate order should be written on the patient's order sheet and the physician should explain in a progress note both the rationale for the decision and the names of those who participated in making the decision. In addition, the order and the note should be very clear regarding what aspects of resuscitation should not be performed. For example, in some cases, the decision will have been to proceed with intubation in the event of respiratory arrest, but not in the event of cardiac arrest; or for

basic CPR for a limited time period with constant communication during the procedure; for others, neither intubation or basic CPR would be considered appropriate. Very careful communication and recommendations should be made by physicians who are responsible for these discussions. The relatively new discipline of palliative care can be very helpful in developing these discussions and clarifying the goals of treatment, including not performing CPR.

For children who have a high risk of cardiopulmonary arrest because of chronic or congenital underlying disease, discussions about resuscitation are best held in an anticipatory way so that there are no hasty decisions required in the event of an arrest. Once a decision has been made about the extent of resuscitation, it is very important that the documentation is available quickly so that these decisions can be honored. This is especially important in schools, child care centers, chronic care facilities, and other settings where an acute arrest can occur and both the staff and emergency medical service providers need to be aware of the decisions that have been made. In many states, such as New York, Maryland, and Pennsylvania, there is a universal Medical Orders for Life Sustaining Treatment (MOLST) form that is signed by physicians.

### SUMMARY

Since the introduction of the technique of basic CPR in the 1960s, many advances have been made in the management of children in respiratory and cardiac arrest. With ongoing research in this area, and with due attention to strategies that would prevent arrests from occurring in the first place, the incidence will likely decrease, and outcomes will improve. However, this circumstance will occur only if cardiac and respiratory arrests are seen as a public health problem that requires universal education and training in prevention, recognition, and basic treatment.

## Appendix B OUTPATIENT PROCEDURES

*Timothy Cornell, MD; John P. Schmidt, MD;  
Joseph R. Custer, MD*

Physicians who perform procedures in children need to be competent in basic procedures as well as the management of the sedated child, a core competency of which is airway management. This appendix addresses patient preparation, sedation and analgesia, sample collection for diagnostic and therapeutic purposes, vascular access for medication and fluid administration, airway management skills, and circumcision.

### PATIENT PREPARATION

The first step in any procedure is to communicate the reason for the procedure to the parents and child. By establishing a clear understanding among parents and child of what is to be done, a physician gains their confidence and facilitates proper care. Honest and accurate descriptions of the steps involved in the procedure allow the parents and child to control some aspects of the procedure (eg, when to start, from which arm to draw blood) and will also instill a greater trust in the physician. Procedures that the physician may consider routine and ordinary have great significance to the parents and child, so all procedures require explanation.

The parents and the patient should be informed about the indications for each procedure, the information that is to be gained from it, the risks of performing (or not performing) the procedures, and any complications that may arise because of the procedure. Parents should be given information about the degree and duration of discomfort and inconvenience their child will experience because of the procedure. Reassurance that the physician understands the child and the child's perceptions must be conveyed to the parents.

The spectrum of ages and ranges of development in children requires an adaptive approach by the physician. Parent and child perceptions and fears will require a calm, empathetic, and reassuring approach. The toddler's fear of pain, of being handled by strangers, and of separation from the parents must be considered. In older children, describing the procedure to them in a developmentally appropriate manner is important. In the older or socially mature child, a contract of cooperation can be established (eg, "You can help by holding very still").

Whether the parents will be in attendance during the procedure should be ascertained before any preparation of the child. Not every parent will want to be present; therefore, participation should be voluntary.

### MONITORING

Safe and efficient performance of a procedure requires monitoring the patient. Some procedures will require sedation for full cooperation of the patient, which necessitates specific monitoring. Monitoring

during sedation should be treated as if the child were undergoing general anesthesia. The American Academy of Pediatrics (AAP) has developed standards of care for monitoring and managing patients before, during, and after procedures. Box B-1 lists monitoring devices and equipment needed for procedures.

Oxygen saturation, heart rate, and respiratory rate must be monitored because children are particularly vulnerable to hypoxemia. The child's respiratory rate, effort, and airway-protective reflexes must be continuously observed.

The presence of an assistant whose only responsibility is to monitor the stability of the patient during the procedure is important for patient safety. This second caregiver's only responsibility should be to monitor the respiratory and hemodynamic status of the sedated child.

### SEDATION AND ANALGESIA FOR PROCEDURES

Sedation may be required for therapeutic as well as diagnostic procedures. The AAP has set the following goals during sedation and analgesia for procedures.

#### Goals for Sedation and Analgesia in Children

The physician who administers sedation must have a complete understanding of the risks, the medications used, and the criteria a patient must meet to discontinue close monitoring. Physicians and caregivers who administer sedation must be both competent and credentialed in airway management. The physician must be comfortable identifying and treating complications, including cardiorespiratory depression, airway obstruction, and emesis in all patients. Patients requiring sedation who have chronic diseases, especially patients who have neuromuscular, pulmonary, cardiac, or renal disease, are at risk for adverse events. Box B-2 lists goals for sedation and analgesia.

#### Assessing Risk

Physicians must identify factors that may place a child at risk for poor outcomes with sedation. The child's medical history, including chronic illness, problems with sedation or anesthesia, allergies to medications, and current signs or symptoms of illness must be fully

#### BOX B-1 Monitoring Devices and Equipment for Procedures

- Pulse oximeter
- Blood pressure cuff
- Cardiorespiratory monitor
- Resuscitation equipment, including resuscitation bag and mask
- Intubation equipment
- Airway suctioning equipment
- Flow sheet for documentation
- Oxygen source and delivery services
- Equipment for intravenous access

investigated. Appropriate fasting times before sedation are given in Table B-1.

The most common complication of sedation is loss of respiratory drive and the ability to protect the airway, leading to hypoxemia. However, the adequacy of a child's airway, and, therefore, the child's risk for airway compromise during sedation, can be estimated.

A physician trained in advanced airway management should be consulted if the child has a potential risk for a difficult airway. Best practices, as characterized in standardized protocols and national guidelines for sedation, reduce the risk of adverse events.

### Medications for Sedation and Analgesia

The type and amount of medication used for sedation will depend on the procedure, the degree of analgesia required, and the experience of the physician in charge of sedation. Some procedures (eg, diagnostic imaging) may require sedation and no analgesia. Other procedures may require only local analgesia and no sedation. Combinations of medications may be required to achieve the desired duration of sedation and analgesia. Because each situation is different, physicians should be familiar with the mechanisms, indications, interactions, contraindications, and side effects of a variety of medications used for sedation and analgesia. Commonly used medications are discussed briefly in this section; thorough reviews are available.

Topical anesthetic creams (eutectic mixture of local anesthetics [EMLA and ELA-MAX]) can provide local analgesia and may be useful as an adjunct to other agents. These creams are applied to the local site and covered with an occlusive patch for anywhere between 45 and 60 minutes for EMLA and 20 to 30 minutes for

ELA-MAX prior to the procedure. Cost and time should be considered when these agents are used. In some children, these creams can reduce the anxiety associated with certain procedures.

Local anesthesia can be produced by infiltration of the skin with lidocaine (1% solution, 10 mg/mL). Systemic effects of local lidocaine are rare, but may have serious consequences that include hypotension, seizures, and respiratory arrest. The maximum dose of locally infiltrated lidocaine is 5 mg/kg (0.5 mL/kg of a 1% solution).

A burning, stinging sensation accompanies infiltration of lidocaine as a result of its low pH. This may be minimized by using lidocaine buffered 10:1 by volume with sodium bicarbonate (1 mEq/mL). Slow injection of the buffered lidocaine also reduces the stinging sensation.

The most commonly used agent for sedation in children is midazolam. It is water soluble and has a rapid onset (1–5 minutes) and a short duration of action (45–60 minutes). It produces good anxiolytic effect and retrograde amnesia. The initial dose of midazolam is 0.05 to 0.1 mg/kg intravenously or 0.5 to 0.75 mg/kg orally. The intravenous (IV) dose may be titrated to effect with a maximum dose of 0.6 mg/kg. Hypotension and respiratory depression (especially when given with opioids) are the most common side effects. The side effects of midazolam, as with any of the benzodiazepines, may be reversed with flumazenil (0.005–0.02 mg/kg intravenously).

Fentanyl is a short-acting opioid that does not cause histamine release, making it an effective analgesic in children. As with all opioids, respiratory depression is the most common side effect; it may be reversed with naloxone (0.1 mg/kg/dose, maximum 2 mg/dose; may repeat every 2 minutes). If naloxone is used to reverse the side effects of opioids, repeated doses may be necessary because its effects are transient. If moderate to severe pain is anticipated, a combination of fentanyl and midazolam may be used. Again, the dose of each should be reduced by one-half if the patient has cardiac, respiratory, hepatic, or renal organ failure.

More potent drugs are available for procedures that will cause intense pain. Ketamine and propofol should be used only by physicians skilled in deep sedation management and experienced in the use of these agents. General anesthesia is a reasonable consideration. Consultation with an anesthesiologist or pediatric intensivist may be helpful.

### BOX B-2 Goals for Sedation and Analgesia

- Guard the patient's safety and welfare
- Minimize physical discomfort or pain
- Minimize negative psychological responses to treatment by providing analgesia and maximize the potential for amnesia
- Control behavior
- Return the patient to a state in which safe discharge, as determined by recognized criteria, is appropriate

**Table B-1** Fasting Guidance for Children Undergoing Sedation<sup>a</sup>

AGE	DURATION OF FASTING FOR MILK AND SOLIDS	DURATION OF FASTING FOR CLEAR LIQUIDS
0–5 mo	4 hr	2 hr
6–36 mo	6 hr	2 hr
>36 mo	8 hr	2 hr

<sup>a</sup>Guidance is for elective sedations. In situations in which emergent sedation is required and the patient does not meet the fasting requirement, the physician must weigh the risk of aspiration against the benefit of the sedation. Securing the airway to help prevent aspiration should always be considered in these situations.

### Discharge Criteria

Approximately 12% of children sedated for a procedure experience a serious adverse event, mainly hypoxemia. Most complications will occur during the procedure itself, but monitoring is necessary after the procedure. All patients should be monitored for a minimum of 30 minutes from the last dose of medication and should meet the criteria developed by the AAP before monitoring is discontinued. Box B-3 lists discharge criteria for children who have been sedated.

#### BOX B-3 Discharge Criteria for Children Who Have Been Sedated

- Cardiovascular function and airway patency are satisfactory and stable
- Patient can be easily aroused, and protective reflexes are intact
- Patient can talk (if age appropriate)
- Patient can sit up unaided (if age appropriate)
- For a very young patient or a child incapable of the usually expected responses, the presedation level of responsiveness or a level as close as possible to the normal level for that child should be achieved
- State of hydration is adequate

### SAMPLE COLLECTION

#### Blood

##### Capillary Puncture

Blood samples may be obtained from the capillary bed of a finger, toe, or heel. After the skin is warmed and prepared with alcohol, a firm stab wound is made with a lancet in the ventrolateral aspect of the distal phalanx, avoiding the pad and joint, or the posterior edge of the heel pad. Frequent wiping may be needed to prevent clotting and to obtain free flow without squeezing. Local pressure applied with dry gauze will stop the bleeding after the sample has been obtained.

##### Venipuncture

Figure B-1 illustrates the location of superficial veins commonly used to obtain blood samples. The largest superficial veins are those of the cervical and femoral areas, although these veins should be avoided for routine blood sampling.

For venipuncture of an extremity, the limb is restrained and the skin is prepared with alcohol. A tourniquet is applied to the extremity above the point of planned venous puncture tightly enough to produce venous stasis and vein distention, yet loosely enough to allow arterial perfusion. A 20- or 22-gauge needle or butterfly needle attached to a syringe may be used. The vein is stabilized by traction on the overlying skin along the longitudinal axis of the vein. The skin is pierced with the needle bevel up. The needle tip is then advanced subcutaneously and the vein is entered with a short jab to prevent its rolling away. Negative pressure

**Figure B-1** Superficial veins accessible for blood sampling and intravenous device placement.

in the syringe is used to withdraw the amount of blood needed. After the blood is obtained, the tourniquet is released, the needle removed, dry gauze applied with pressure to the site, and the extremity elevated for 1 or 2 minutes to prevent bleeding at the puncture site.

### Arterial Puncture

Assessment of the arterial blood gasses is essential in monitoring and diagnosing a variety of cardiopulmonary diseases. The radial artery is the preferred site for arterial puncture. It is in a consistent anatomic position and is well fixed by surrounding connective tissue. Arterial punctures may be complicated by arterial laceration, spasm, or hematoma.

The wrist is supported in a position of supination and slight dorsiflexion. The artery may be located at the wrist by feeling for the point of maximum pulsation. In newborns, it is usually found along the first flexor crease, at one-sixth of the width of the wrist measured from its radial edge (Figure B-2).

The size of the needle used varies with the patient's age (25-gauge for newborns and infants to 22-gauge for older children and adolescents). Care must be taken to avoid compressing the artery during restraint. The syringe is held as a pencil or dart would be held, and the needle is introduced into the artery at approximately a 45-degree angle. A flash of blood spurting into the syringe indicates a successful puncture. Gentle aspiration is required when a syringe is used. Many individuals find that performing the procedure with a butterfly needle is easier, especially in infants. Once collected, the sample should be sealed and any air bubbles removed, and then the sample should be placed on ice and sent to the laboratory for analysis.

### Cerebrospinal Fluid

The need to perform a lumbar puncture to rule out meningitis and other central nervous system infections must be weighed against the dangers inherent in performing a lumbar puncture in the presence of

increased intracranial pressure. Increased intracranial pressure is a contraindication to lumbar puncture. Its presence dictates immediate neurosurgical consultation if collection of cerebrospinal fluid (CSF) is judged clinically necessary. Coagulopathy and thrombocytopenia are relative contraindications to lumbar puncture. If meningitis is suspected, antimicrobial therapy should be initiated promptly.

The position of the patient during lumbar puncture varies. Some physicians prefer infants to be held upright, whereas others prefer the lateral recumbent position (Figure B-3). Local or topical anesthetic (or both together) will assist in ensuring a painless procedure. Reassurance and clear communication with the older child is as important as the local anesthetic.

The preferred site is the L3-L4 interspace. It is located by determining the site at which an imaginary line drawn between the superior edge of the right and left iliac crests crosses the spine. The interspace above and below the L3-L4 space may also be used. The skin is prepared with appropriate antiseptic, and the site is draped. The person performing the procedure wears sterile gloves and a mask.

Care must be taken so that the needle enters the intervertebral space in the sagittal plane. This target requires several different perspectives of the proposed line of entry. A way to achieve this with a child in the lateral recumbent position is to make sure the line drawn between the superior edge of the right and left posterior iliac crests is perpendicular to the examination table. For a child in the upright sitting position, this line should be parallel with the surface of the examination table. The spinal needle is then advanced perpendicular to this line into the L3-L4 interspace aimed toward the umbilicus.

Once the skin is penetrated, the needle is advanced slowly in the sagittal plane. Although a distinct pop may be felt in older patients when the dura is pierced, such is not the case in infants. When the physician suspects that the spinal canal has been entered, the

**Figure B-2** Radial artery puncture. The position of the radial artery is determined by palpation.

**Figure B-3** Positioning an infant or a toddler for a lumbar puncture.

stylet is removed and the needle gently rotated to maximize the flow of CSF through the needle. If no flow is obtained, the stylet is reinserted and the needle is advanced further or is withdrawn and redirected. Care must be taken to avoid a so-called *bloody tap*, or *traumatic tap*, caused by pushing the needle into the venous plexus along the anterior wall of the spinal canal. A syringe should never be used to enhance the aspiration of CSF.

A stopcock and manometer are attached to the spinal needle to measure the opening and closing pressure. One milliliter of fluid is collected in each of 4 sterile test tubes to be used for bacteriologic, chemical, and cytologic determinations. In the case of a traumatic tap, the red cells in the first and fourth tubes should be counted. A traumatic tap usually results in fewer red cells in the latter tube. Blood from a central nervous system hemorrhage will have the same number of red blood cells in both samples. Once the fluid is collected, the stylet is replaced and the needle withdrawn. Direct pressure is applied to the puncture site.

## Urine

### Urethral Catheterization

To collect a sterile specimen of urine from a child who cannot produce a midstream, clean-catch, voided specimen, or to monitor urine output continuously, a catheter is inserted into the bladder through the urethra. The child is placed supine in a frog-leg position and prepared with sterile technique, including drapes, gloves, and skin cleansing. A small (8 French) straight or indwelling catheter should be used for a child; a No. 5 feeding tube may be used for an infant. The catheter or tube should be coated with sterile lubricating jelly. For a girl, the labia majora and minora are widely separated and the urethral meatus is identified, cleaned, and entered with the catheter. For a boy, the penis is held at a right angle to the abdomen while the catheter is placed in the urethra and advanced until urine is obtained. If the catheter is to remain in place, the balloon should be filled with sterile saline or water and connected to a closed, sterile collection system.

The catheter should not be forced at any time during the procedure. Damaging the urethra in both boys and girls is possible if the catheter is forced against resistance. Extreme care must be exercised in children with coagulopathy. Strict adherence to sterile technique will reduce infectious complications.

### Percutaneous Suprapubic Bladder Aspiration

A suprapubic bladder aspiration can be performed to obtain a sterile urine specimen. To ensure that there is adequate urine in the bladder, this procedure should not be attempted if the child has voided in the previous hour. An assistant holds the child in the supine frog-leg position while the operator percusses the bladder above the symphysis pubis and cleans the skin. To prevent urination during the procedure, the urethra should be compressed by pressure through the rectum of a girl or by direct pressure to the penis of a boy. The abdominal wall is entered in the midline 1 to 2 cm above the symphysis pubis with a 22-gauge, 1-inch needle attached to a syringe (Figure B-4). The needle

should be directed slightly cephalad and negative pressure maintained in the syringe as it is advanced.

The procedure may be repeated once if no urine is obtained with the first attempt. If the repeat attempt is unsuccessful, an hour should be allowed to elapse before trying again. When urine is obtained, the needle is withdrawn and the entry site is covered with a dry dressing. Complications include transient hematuria and, rarely, perforation of the bowel.

## Middle-Ear Fluid

Tympanocentesis is most often performed to obtain cultures of middle-ear fluid. It may be particularly important for identification of persistent or refractory infection in the immunocompromised child. Tympanocentesis is contraindicated if the child has a bleeding disorder.

The child should be appropriately restrained by the assistant, who should hold the child's head absolutely immobile. The otic canal is cleansed with alcohol, and topical anesthetic should be placed in the canal. After cleansing and before the puncture, specimens should be taken from the ear canal and cultured to identify contaminating organisms.

The tympanic membrane is visualized through the open-ended otoscope. A 3.5-inch, 20- or 22-gauge spinal needle with a double bend (Z-shaped) allows clear visualization of the tip and the membrane. The needle puncture is made in the posterior inferior quadrant of the tympanic membrane. Gentle negative pressure is applied to withdraw middle-ear fluid. If no aspirate is observed, the needle can be flushed with nonbacteriostatic sterile saline into culture media.

## Pleural Fluid and Air

Pleural fluid can be analyzed for diagnostic purposes. In patients with large effusions, fluid removal may improve gas exchange. The same technique can also be used for the emergency relief of a tension pneumothorax. The site is determined by radiograph and by findings at physical examination. Ultrasound examination may help to determine the location of an effusion. When fluid is removed from the bases of the lungs, care must be taken to avoid damaging abdominal viscera. Anteroposterior, side up-side down, and lateral radiographs may aid in

**Figure B-4** Bladder tap for suprapubic aspiration of urine. The index finger of the opposite hand locates the symphysis pubis.

the determination of position and suggest the presence of loculated fluid.

The complications of thoracentesis include pneumothorax, hemothorax, and introduction of infection. Laceration of the abdominal viscera through the diaphragm can be avoided by appropriate selection of the puncture site. Removal of large amounts of fluid can result in hemodynamic compromise. Re-expansion pulmonary edema is a rare complication of fluid removal, but should be suspected in patients who develop tachypnea and hypoxemia after a pleurocentesis.

The positioning of the child depends on whether the anterior or posterior aspect of the chest is to be entered. The older child should be seated and leaning forward, either against the back of a chair or leaning on a bedside table. An infant or small toddler may be held in a hugging position against an assistant's chest.

The sites used for drainage of a pleural effusion or aspiration of free air include the anterior, middle, or posterior axillary line in the fourth, fifth, or sixth intercostal space. Other sites may be selected as dictated by the location of loculated collections of fluid. These sites may be selected with ultrasound guidance. A skilled radiologist can perform a computed tomography-assisted aspiration in difficult cases.

A wide area is prepared with an appropriate antiseptic, and with a 25-gauge needle, local anesthetic is infiltrated over the body of the rib just below the intended puncture site. The needle is inserted into the skin overlying the rib and then moved over the surface of the rib upward to the interspace while gentle aspiration is alternated with infiltration of the anesthetic solution so that the subcutaneous tissues and the pleura are anesthetized. The intercostal blood vessels and nerves lie along the inferior margin of each rib and can, therefore, be avoided by this approach.

Materials are simple—an 18- or 22-gauge plastic over-the-needle catheter, a sterile 50-mL syringe, a 3-way stopcock, and an appropriate sample container. The needle and catheter are advanced along the previously described tract, with gentle suction applied to the syringe. When the pleura are entered, the plastic cannula is threaded over the needle and advanced into the pleural space. A 3-way stopcock is attached to the catheter, and fluid is aspirated and placed in appropriate containers for Gram stain and culture. Pleural fluid may also be examined for white blood cells and differential counts, pH, protein, glucose, lactate dehydrogenase, and cell cytology as appropriate.

An alternative to needle thoracostomy for drainage of effusions is placement of a pigtail catheter or chest tube by use of a modified Seldinger technique. This method has the benefits of being easy and safe. A kit is available that contains the catheter, dilator, introducer needle, guidewire, and an adaptor that connects the catheter to large-bore rubber tubing for continuous suctioning. This system can remain in place as an indwelling catheter if needed for continual drainage of fluid or air collections. This is a relatively painful procedure, so appropriate sedation and analgesia may be required.

The tube is inserted by first advancing the needle over the superior margin of a rib, usually T4 to T6, in the midline or anterior axillary line, into the pleural

space. Immediately after entering the pleural space, a guidewire is advanced through the needle into the pleural cavity. A small stab wound, 2 to 4 mm in diameter, is made at the site where the guidewire enters the skin. A hard polyurethane dilator is advanced over the wire. This dilator enlarges the tract to facilitate passage of the pigtail catheter. With the wire position fixed, the dilator is withdrawn. The catheter is threaded over the wire and advanced into the pleural space; then the wire is withdrawn. The catheter is attached to the large-bore tubing and placed on the appropriate suction device. The pressure in the suction device should be set at 15 to 20 cm H<sub>2</sub>O. Chest radiographs document the position of the catheter. The catheter is secured to the chest with a small adhesive dressing or simply sutured in place.

### Pericardial Fluid and Air

Pericardiocentesis is a high-risk procedure, but it can be lifesaving. The dangers of this procedure must be weighed against the urgency of diagnosing a pericardial effusion or an unchecked cardiac tamponade. In nonurgent situations, consultation with a cardiologist or intensivist is suggested. Complications of the procedure include myocardial injury, laceration of a coronary artery, cardiac arrhythmia, and infection. The internal mammary arteries are within 2.5 cm of the sternal border and may also be damaged.

The alternate points of entry into the chest are illustrated in Figure B-5. The preferred site is at the left

**Figure B-5** Two sites for aspiration of fluid or air from the pericardial sac.

chondroxiphoid angle. Whenever possible, fluoroscopy or echocardiography should be used for guidance.

The patient should be supine at approximately a 30-degree angle and carefully restrained with appropriate cardiorespiratory monitoring. Appropriate sedation and analgesia will be needed. A wide area is prepared with antiseptic. The entry site is infiltrated with lidocaine. A 50-mL syringe is connected to a 3-way stopcock and an 18-gauge needle. The needle is directed inward and medially when the intercostals approach is used. When the chondroxiphoid approach is used, the needle is aimed upward and posteriorly. Gentle negative pressure should be applied to the syringe as the needle is advanced. The fluid should be aspirated slowly. The needle is withdrawn, and a simple sterile dressing is applied over the puncture site.

A modified Seldinger technique may be used to place a pigtail catheter for long-term drainage of a pericardial effusion.

### Vascular Access

#### Emergency Intravenous Access and Protocol

The small size of the child, the stress of the situation, and venous collapse make insertion of a peripheral IV device difficult in the critically ill child. A protocol approach to the problem of establishing venous access has been suggested. In a series of pediatric resuscitations, more than 10 minutes was required to establish venous access, and, in 6% of the subjects, no access could be established. Best-practice guidelines suggest that in the treatment of shock, attempts at peripheral vein insertion should be limited to 90 seconds, and then an intraosseous device should be placed.

Current recommendations and standards of care guidelines for shock and cardiorespiratory arrest mandate the early use of the intraosseous needle in emergent situations. Undue time should not be spent on attempts at placing peripheral or central venous lines when no other vascular access is present. All physicians who treat children should familiarize themselves with this technique.

#### Intraosseous Infusions

Intraosseous infusion is a procedure that should be familiar to all who provide care to children. It can be used in the care of a critically ill child younger than 6 years whenever a delay in establishing venous access might compromise the patient. Treatment should not be delayed while waiting for central access. The ability to place an intraosseous needle allows even a technically inexperienced person to gain immediate access to the intramedullary venous system, which is continuous with the venous circulation. Crystalloid and colloid for fluid resuscitation, blood, plasma, catecholamines (eg, epinephrine, dopamine), glucose, calcium, and sodium bicarbonate can all be administered by the intraosseous route. Intraosseous needles manufactured specifically for this purpose should always be available.

The preferred sites are the anterior medial surface of the proximal tibia and the medial surface of the distal tibia proximal to the medial malleolus (Figure B-6, Figure B-7, Figure B-8). The iliac crest, sternum, and femur are alternative sites. The epiphysis must be avoided when the proximal tibia is used. The cortex in

the midshaft of the tibia is difficult to penetrate, although it is sometimes used in emergencies. In a child older than 6 years, the thick cortex at the proximal and distal tibia prevents use of these sites.

The site is aseptically prepared. The needle is advanced perpendicular to the bone, with firm pressure in a rotary motion. Entry to the marrow cavity is detected by decreasing resistance. Aspiration with a syringe should produce blood and marrow. To clear the needle, it should be flushed with 3 to 5 mL of sterile saline in a sterile syringe. Resuscitative medications

**Figure B-6** Intraosseous needle in position in the medullary sinusoids. Marrow aspiration documents correct placement. (From Spivey WH. *Intraosseous infusions*. J Pediatr. 1987;111:639–643. Reprinted with permission.)

**Figure B-7** Insertion of intraosseous needle at the proximal tibia. The tibial tuberosity and the medial border of the tibia are palpated. The needle is inserted halfway between these 2 points and 1–2 cm distal, pointing in a caudal direction away from the joint space. (From Spivey WH. *Intraosseous infusions*. J Pediatr. 1987;111:639–643. Reprinted with permission.)

should be flushed with 3 to 5 mL of saline. The device is then connected to standard IV tubing. The flow rate should be steady, and the site must be frequently monitored for extravasation. If the needle dislodges or fluid extravasates, the opposite leg should be used. Compartment syndrome has been described when fluid extravasates into soft tissue of the leg. This complication can be limited by changing the site if evidence exists of edema or vascular compromise.

### Percutaneous Intravenous Infusions

The location of accessible superficial veins suitable for percutaneous IV infusions is demonstrated in Figure B-1. All physicians who care for children should be adept at gaining percutaneous intravascular access. Early fluid resuscitation decreases mortality in critically ill children. The veins of the extremities and scalp are commonly used; the latter have no valves and can be punctured in either direction. Skin preparation should be especially meticulous when scalp veins are used because they communicate with the dural sinuses through emissary veins.

The child is positioned and immobilized. A tourniquet is applied above the vein to be infused, and the

skin is cleaned with alcohol. A 20- to 24-gauge percutaneous needle catheter is used to pierce the skin. The vein is then punctured, and when blood is seen in the hub of the needle, it is stabilized and the catheter sleeve advanced into the vein. When the vein is entered, the tourniquet is removed and blood flow is tested. Saline is then injected through the catheter to check for extravasation.

### Heparin Lock

An IV catheter may be converted to a heparin lock for intermittent administration of medications. Heparin in normal saline solution is used to flush and fill the catheter and tubing. A concentration of 10 U/mL of heparin prevents clotting within the catheter without affecting the patient. Prolonged use of any indwelling device carries the risk of local and disseminated infection.

### Peripherally Inserted Central Venous Catheters

Peripherally inserted central catheters (PICCs) can be inserted in larger peripheral veins and provide a safe route for long-term alimentation, antibiotics, medication, and hypertonic fluid therapy that are more appropriately delivered to the central circulation. The Centers for Disease Control and Prevention recommend the use of these catheters as an alternative to surgically placed or traditional central venous catheters for long-term use. Data suggest that the use of PICC lines may reduce infectious and thrombotic complications. These catheters are composed of biologically inert silicone or polyurethane. Specialized PICC lines have been designed to be used with rapidly infusing contrast systems used for computed tomography scans. In many institutions, they are placed by nurses with special training.

Complications are similar to other types of central catheters, but are rare, reported to occur in 3% to 10% of centrally placed catheters. Expected duration of use is nearly 2 weeks. Catheters with tips placed in a non-central location seem to have a higher rate of complications (most commonly thrombosis). PICC catheters are commonly placed in the large veins in the antecubital fossa or the basilic vein of the upper arm. In neonates and young infants, smaller PICC lines can be inserted in the saphenous vein or in scalp veins. They are available in numerous sizes and with multiple lumens for children of various ages (Table B-2).

**Figure B-8** Insertion of the intraosseous needle in distal tibia. The needle is inserted at the junction of the malleolus and the tibial shaft. The tip is aimed away from the joint space. (From Spivey WH. *Intraosseous infusions*. J Pediatr. 1987;111:639–643. Reprinted with permission.)

**Table B-2** Venous Catheter Sizes

AGE	PICC	FEMORAL VEIN CATHETER	SUBCLAVIAN VEIN CATHETER	INTERNAL JUGULAR CATHETER
Newborn	24-gauge	3 F	3 F	3 F
3–12 months	3 F	4 F	4 F	4 F
1–4 years	4 F	4 or 5 F	4 or 5 F	4 or 5 F
4–8 years	5 F	5 F	5 F	5 F
Adolescent	6 F	7 F	7 F	7 F

F, French

PICC lines are longer than other central catheters and are, therefore, more useful for long-term delivery of medications and other therapies than for rapid fluid resuscitation.

PICC line placement is similar to other central catheter placement and uses the modified Seldinger technique as described previously. The catheter must be cut to the appropriate length to reach the central circulation. The thin stiffening guidewire within the catheter must be pulled back to the desired length prior to cutting the catheter. The vein to be cannulated may be identified by palpation or with the use of ultrasound guidance. A tourniquet is used to increase the size of the peripheral vein. The vein is accessed with either the introducer needle or a standard peripheral IV. A wire is passed through either the introducer needle or peripheral IV. The introducer needle or peripheral IV is removed while leaving the wire in place. Unlike with other central catheters, a peel-away dilator is then introduced over the wire after nicking the skin. Some peel-away dilators are designed to be placed using standard peripheral IV insertion technique without a wire. Once the dilator is in place, the wire and inner cannula are removed. The trimmed catheter is inserted into the peel-away dilator, which is peeled away as the catheter is advanced to its desired position.

### Central Venous Catheters

In general, central venous catheters are used in critically ill children. These catheters may be necessary for fluid administration, maintenance of cardiac output and blood pressure by direct infusions of vasoactive drugs, and central venous pressure and venous oxygen saturation monitoring. A central venous catheter is not immediately required for resuscitation. In this situation, an intraosseous device is recommended. However, in advanced stages of shock therapy, central venous pressure and central venous oxygen saturation measurements are invaluable in evaluating and choosing treatment options.

Complications of central venous cannulation include bleeding, infection, inadequate venous drainage, thrombus formation, and inadvertent penetration of viscera or a vessel wall. The incidence of inadvertent penetration of viscera or other vessels has been reduced by the use of ultrasound by experienced physicians. These complications must be weighed against the benefits of obtaining secure, large-bore venous access, the need to determine the central venous pressure, and the need to measure oxygen saturation. The incidence of catheter-related infections has been reduced with the introduction of catheters impregnated with antimicrobial drugs. Deep-vein thrombosis is a frequent complication of indwelling central vascular catheters. The risk of occurrence of a deep-vein thrombosis is related to young age and the presence of cancer. The peak timing of detection is within 4 days of insertion. If swelling is detected in an extremity in a child with a central vein catheter, deep-vein thrombosis should be suspected, and ultrasonography should be performed. Catheters manufactured with heparin bonding have been reported to reduce thrombosis and infection.

### Femoral Vein Catheter Placement

The femoral vein is a safe, easily accessible vessel for cannulation with a single- or multiple-lumen catheter. With reasonable care, it can be used for relatively long-term access as well, although the longer the catheter is in place, the higher the risk is for a bloodstream infection. Thrombosis is a potential complication. The consistent anatomy of the area and proximity to the femoral arterial pulse allow the vessel to be easily located, because it lies 1 to 2 cm medial to the artery and 2 to 4 cm below the inguinal ligament (Figure B-9). It is usually easy to visualize by bedside ultrasound, even in obese or hypotensive patients. Most bedside ultrasound devices have a Doppler function that makes it easier to distinguish between the femoral vein and femoral artery. The vein will be larger, compressible, and less pulsatile. When the femoral artery pulse cannot be located because of obesity or hypotension, the femoral artery can be easily confused with the vein and inadvertently catheterized. A transcutaneous Doppler or bedside ultrasound can facilitate placement.

The patient should be supine, and the groin should be widely prepared with an appropriate antiseptic

**Figure B-9** Approach to the femoral vein. The patient is flat and supine, with the thigh slightly abducted and externally rotated. The introducer needle enters the skin 2 to 3 cm distal to the inguinal ligament and 0.5 to 1 cm medial to the pulse of the femoral artery. (From Schexnayder SM, Storm EA, Stroud MH, et al. *Pediatric vascular access and centeses*. In: Fuhrman BP, Zimmerman JJ, Carcillo JA, et al, eds. *Pediatric Critical Care*. 4th ed. Philadelphia, PA: Elsevier Saunders; 2011:154. Reprinted with permission.)

agent. For infants, a towel roll under the hips can facilitate access to the vein. Sterile technique, including gloves, gowns, and masks, and a sterile sleeve for the ultrasound probe are important for preventing infections. The femoral artery is palpated 2 to 4 cm below the inguinal ligament; the vein is 1 to 2 cm medial to the artery. The skin and immediate subcutaneous tissues are infiltrated with 1% lidocaine.

The operator must be familiar with the use of the modified Seldinger technique for percutaneous placement of a catheter over a guidewire, which is placed through an introducer needle (Figure B-10). Manufacturer-supplied kits containing an introducer needle, dilator, guidewire, and catheter are available. The appropriate-sized catheter has an outer diameter of 3F to 4F for patients under 1 year of age, 5F to 6F for children 1 to 7 years old, and 7F for children 8 years or older. A syringe that contains 2 to 3 mL of heparinized saline is attached to the introducer needle. The needle is introduced at a 30- to 45-degree angle from horizontal and aimed at the umbilicus. Care should be taken to avoid advancing the needle beyond the inguinal ligament because the peritoneum, bowel, and bladder can be perforated. Its tip should be visualized on the ultrasound image and can be followed into the vessel. The needle tip can often be seen indenting the vessel wall substantially, and it is not uncommon to get blood flow or needle visualization in the lumen of the vessel until the needle is gently pulled back. With continuous, gentle aspiration, the needle is advanced into the vein. When good blood return is documented, the syringe is removed. The guidewire is then advanced into the vein. Resistance to the passage of the wire should be minimal (if resistance is encountered, the needle and wire must be removed simultaneously to prevent shearing the wire off in the patient's vein). The needle is then withdrawn, leaving the wire in place. An incision, 2 to 4 mm deep, is made with a scalpel at the point where the guidewire enters the skin. A dilator is threaded over the wire and passed through the skin and subcutaneous tissue and into the vessel. It is then withdrawn, leaving the wire in place. The catheter is threaded over the wire. Care must be taken to ensure that at least 1 to 2 cm of the guidewire extends from the proximal end of the catheter before it is threaded into the vein; otherwise, the wire can be lost in the vessel. The physician, being careful to avoid changing the position of the wire, slowly advances the catheter over the wire to the desired distance, and then removes the wire. The catheter is then sutured in place. The position should be verified by radiography. Each lumen in the catheter should flush and aspirate easily.

### Subclavian Vein Catheter Placement

The subclavian vein is readily accessible. Risks include pneumothorax or accidental penetration of the subclavian artery, hematoma formation, hemorrhage, and thrombosis. The risk of this procedure must be balanced with the skill of the physician and the benefit to the patient.

Catheterization kits containing an introducer needle, dilator, guidewire, and catheter are available.

**Figure B-10** A, Guidewire is placed through the introducer needle into the lumen of the vein. B, Catheter is advanced into the vein lumen along the guidewire. C, Hub of the catheter is secured to the skin with suture. (From Schexnayder SM, Storm EA, Stroud MH, et al. *Pediatric vascular access and centeses*. In: Fuhrman BP, Zimmerman JJ, Carcillo JA, et al, eds. *Pediatric Critical Care*. 4th ed. Philadelphia, PA: Elsevier Saunders; 2011:152. Reprinted with permission.)

The appropriate-sized catheter has an outer diameter of 3F for infants, 4F for toddlers, 5F for children aged 4 to 12 years, and 7F for adolescents. The right subclavian vein is preferred over the left because of its more direct entry to the superior vena cava, and because the risk is reduced of pneumothorax (the right lung lies lower in the thorax than the left) and injury to the thoracic duct, which lies in the left hemithorax.

**Figure B-11** Approach to the subclavian vein. The patient is supine, in slight Trendelenburg position, with a small roll along the spine between the shoulders. The needle enters the skin at the junction of the lateral and middle thirds of the clavicle and is directed toward the sternal notch in the horizontal plane. (From Schexnayder SM, Storm EA, Stroud MH, et al. *Pediatric vascular access and centeses*. In: Fuhrman BP, Zimmerman JJ, Carcillo JA, et al, eds. *Pediatric Critical Care*. 4th ed. Philadelphia, PA: Elsevier Saunders; 2011:154. Reprinted with permission.)

The patient is restrained and placed in the Trendelenburg position. The child's face is turned 90 degrees away from the intended puncture site. A 3-inch towel roll is placed along the long axis of the thoracic spine between the shoulder blades. The area overlying the puncture site is cleansed widely, and drapes are used to provide an aseptic field. Masks, gloves, and gowns are used. The infraclavicular approach is simpler for most physicians to learn (Figure B-11). The vein lies approximately parallel to the proximal third of the clavicle. The subclavian artery runs posterior to the vein beneath the anterior scalene muscle. The skin overlying the puncture site and intended tract is infiltrated with 1% lidocaine.

The introducer needle is placed just medial to the midclavicular line 2 to 3 cm below the inferior border of the clavicle. The needle is aimed toward the mid-sternal notch and is advanced to the inferior border of the medial position of the clavicle. A syringe containing a few milliliters of saline is attached to the introducer needle, and negative pressure is applied to the barrel of the syringe; the needle is advanced deep to the clavicle on a course nearly parallel to its medial portion. Small cephalad adjustments of the target point (approximately 0.25-cm increments) can be made if the vein is not entered immediately.

When the vein has been entered, as evidenced by blood entering the syringe, the hub of the introducer

needle should be held securely in place and the syringe removed. Caution must be exercised because air may be introduced into the vein as the patient increases the negative pleural pressure when initiating a breath. Therefore, the proximal orifice of the needle must be temporarily occluded by placing a finger over the opening.

The flexible, spring-loaded end of the guidewire is inserted into the introducer needle and advanced through the bore of the needle into the subclavian vein and subsequently into the superior vena cava. A minimum of 3 cm of wire is passed beyond the estimated tip of the needle. A cardiac arrhythmia may signal that the guidewire has been passed too far into the right ventricle, in which case it should be drawn back. The proximal end of the wire should be held securely as the introducer needle is removed.

The catheter is flushed with heparin solution and advanced over the guidewire after the skin and subcutaneous tissues have been stretched with the dilator. Once the catheter is in the desired position, the wire is removed. The proximal end of the catheter is attached to the central venous pressure monitoring or IV fluid administration system. The catheter is sutured into place and covered with a sterile dressing.

Placement should be verified by radiography. The typical a, c, and v wave of a central venous catheter should be present. The catheter should flush and aspirate blood with ease. The tip of the catheter should be in the distal third of the superior vena cava, above the junction with the right atrium.

### **Umbilical Vessel Catheter Placement**

Catheterization of the umbilical vein is useful in newborns for emergency correction of acidosis, hypoglycemia, and hypotension and for the measurement of central venous pressure. The complications of umbilical vein catheterization include sepsis and micro-embolization from catheter-induced thrombosis. An umbilical venous catheter can be easily misplaced into a branch of the portal venous system, and injecting hyperosmolar solutions that contain substances such as glucose or sodium bicarbonate can lead to portal-vein thrombosis and hepatic necrosis. Umbilical vein catheters have also been implicated in cases of necrotizing enterocolitis and spontaneous perforation of the bowel.

Manufactured kits are available, and the catheter size is based on the patient's weight: a 3.5F catheter should be used for infants weighing less than 1,500 g and a 5F catheter for those weighing more than 1,500 g. The small premature infant is susceptible to chilling during the procedure; thus, a radiant warmer should be used. Special attention to aseptic technique—surgical scrubbing of the operator's hands, antiseptic preparation of the baby's abdomen and umbilical cord, and maintenance of a sterile field—is essential. The physician should be gloved, masked, and gowned.

The catheter is measured to determine the length of insertion by measuring the distance from the infant's shoulder to the umbilicus by the conversion method shown in Figure B-12. This length ideally places the catheter at the junction of the inferior vena cava and

the right atrium. Care must be taken to avoid covering the infant's chest in such a manner that apnea or malfunction of the heat probes or monitor leads will go undetected.

An assistant provides gentle traction to the cord stump while the physician transects the cord with a scalpel 1 to 1.5 cm above the skin. Gauze sponges should be available for tamponade to control oozing of blood from the umbilical vein; the amount of oozing is usually insignificant. The cord stump is inspected to locate the thin-walled umbilical arteries. The catheter is attached to a 3-way stopcock and a syringe containing heparinized saline solution. The catheter is flushed with the heparin solution. Minimal traction on the superior edge of the cord stump may be helpful in locating the orifice of the umbilical vein; this is gently dilated with pickup forceps or a small probe, and the catheter is inserted the predetermined distance. Resistance is occasionally met at the level of the abdominal wall or at the level of the ductus venosus. Gentle pressure and partial withdrawal and rotation of the catheter usually overcomes this resistance; force should not be used. The position of the catheter should be verified by radiograph except under emergency circumstances.

Care must be taken to avoid iatrogenic blood loss through accidental dislodgement of the catheter, which can be prevented by making a purse-string suture around the umbilical stump and carefully taping the catheter to the abdominal wall. A bridge made of adhesive tape (Figure B-12) and supplemented with a purse-string suture or umbilical tape will secure the catheter.

### Airway Management

Hypoxemia is a common and preventable complication of sedation and a frequent consequence of illness

**Figure B-12** Umbilical vessel cannulation. The hemostat is used to grasp the edge of the cord stump, which is then rolled toward the operator. A probe may be used to dilate the orifice of the vessel. The inset demonstrates a bridge of adhesive tape to fix the catheter in position.

in children. All health care providers involved in the care of children should master basic techniques of airway management. Basic airway maintenance skills, including jaw-thrust maneuvers, placement of nasal or oral airway, and bag-mask ventilation, are essential for all providers of health care to children. In rescue scenarios, bag-mask ventilation has been demonstrated to be as effective as intubation in influencing morbidity and mortality. Pediatric Advanced Life Support (PALS) courses and provider manuals are excellent sources for a more thorough review.

### Oral Airway Placement

Oral airway placement may be required in deeply sedated patients who have intact respiratory drive, but who have lost control of the upper airway. Oral airways should not be placed in conscious and semi-conscious patients because their placement may induce vomiting and aspiration of gastric content. If a child has an intact gag reflex, a nasopharyngeal tube is a better choice.

Size is crucial, given that misplacement will exacerbate, not relieve, airway obstruction. The appropriate size is estimated by holding the airway next to the patient's face. With the flange of the airway at the lips of the child, the distal end should end at or just distal to the angle of mandible. Airway management tackle boxes and emergency carts should be stocked with an array of sizes for all age groups. The airways range in size from 4 to 10 cm in length. For this and all airway support techniques, including intubation and mask ventilation, position of the head and neck is crucial. The head and neck should be in the so-called *flower-sniffing* position except in neonates and infants, whose large occiputs necessitate the use of a shoulder roll. A thin pillow or folded towel under the occiput usually aids in positioning. A tongue depressor holds the tongue at the floor of the mouth when placing the airway. The position of the head and neck must be maintained after the airway is placed.

### Nasopharyngeal Airway Placement

Nasopharyngeal airways are useful when airway obstruction is caused by lack of tone in the upper pharynx. These airways can be used in conscious children and are available as specially manufactured soft tubes. An endotracheal tube can be shortened at the bedside and used as a substitute. The standard diameter fitting of the endotracheal tube must be firmly replaced if the tube is shortened. These can be placed in a child with a gag reflex. If the child exhibits no gag reflex, the oral airway is preferred.

The diameter should be chosen to prevent blanching of the alae nasae, which indicates compromised blood flow. The length is chosen by estimating the distance from the nostril to the tragus of the ear. Lubrication will ease passage. Care must be taken to avoid lacerating mucosa or the adenoids. If the device is too long, coughing, laryngospasm, and vagal-induced bradycardia may result. These devices have a narrow internal diameter, and therefore patency is difficult to maintain; in addition, they may become obstructed with secretions, blood, and vomitus.

### Bag-Mask Ventilation

Bag-mask ventilation is an essential skill for physicians who care for children. In addition to being the best rescue technique, it is an essential component of airway management. Proper use of this technique preserves patient safety until personnel skilled at intubation are available. Tracheal intubation may not be advisable outside the hospital setting. PALS provides a thorough learning experience. Practice with patient simulators and mannequins can reinforce skill in the technique.

An appropriate-sized mask reaches from the bridge of the nose to just below the lower lip. The self-inflating bag should be large enough to provide an adequate tidal breath for the child; such bags are sized for infants, children, or adults. They can be used without an oxygen source, but in most rescue situations they are used in conjunction with an oxygen source.

There are 2 types of self-inflating bags available—with and without an oxygen reservoir. The distinction between the types is important. In a bag with an oxygen reservoir, the concentration of oxygen in the bag is 100%, and, with compression, 100% oxygen is delivered to the patient. In a bag without an oxygen reservoir, the bag is reinflated with a mixture of room air and 100% oxygen; therefore, less than 100% oxygen is delivered to the patient, generally 30% to 80%, depending on the oxygen flow rate chosen. A flow rate of 10 to 15 L/min is required to maintain adequate volume in the bag.

In the so-called E-C rescuer technique for hand and finger placement, which is taught in PALS provider courses and which is easily mastered, the third, fourth, and fifth fingers form an inverted capital letter E; this supports and lifts the mandible while the thumb and forefinger form a C around the mask (Figure B-13).

**Figure B-13** E-C technique for single-rescuer bag and mask ventilation. The thumb and index finger form a letter C at the base of the face mask, and the other 3 fingers form the letter E, lifting the jaw and sealing the mask to the face while avoiding compression of the neck, which would obstruct the airway. (From American Heart Association. Web-based integrated 2010 & 2015 American Heart Association guidelines for cardiopulmonary resuscitation and cardiovascular care. Part 11: pediatric basic life support and cardiopulmonary resuscitation quality. Reprinted with permission. © 2015 American Heart Association, Inc.)

To maintain airway patency, the child should be placed supine with the head in a neutral position. After connecting the mask to the bag, the flow of oxygen should be confirmed. The mask is placed on the face of the child so that it covers both the nose and mouth. The index finger and thumb should be opposed encircling the base of the mask. The third, fourth, and fifth fingers of the same hand should be placed along the angle of the jaw. The jaw should be brought up into the mask, creating a tight seal. Care must be taken to ensure that no leaks exist around the mask and that the chest rises adequately. Positioning of the head and neck and the use of an oral airway may be helpful if an appropriate seal and breath cannot be achieved.

The 2-handed technique is better than the single-rescuer method and should be used whenever possible. A rescuer uses both hands to seal the mouth and face to the mask and position the head and neck while the second rescuer uses both hands to compress the bag.

### Endotracheal Intubation

The key to success in endotracheal intubation is approaching the procedure calmly and deliberately, with a much-practiced technique and properly prepared and available equipment. Reliably predicting patients who cannot be intubated or patients in whom the intubation will be difficult is possible. For such patients, a clear documentation of the existence of a potentially difficult airway should be conspicuously placed in the record. Skilled personnel should be alerted and a care pathway chosen should an airway emergency arise. Sample critical airway management pathways have been described. Complications of intubation are seen in Box B-4.

Protection of the airway and adequate oxygenation guarantee safe and successful intubation of the airway. Medications undoubtedly improve patient safety. Atropine administered before intubation minimizes the side effects of vagal stimulation (bradycardia) and may be considered as a preintubation medication. The use of neuromuscular blockade to reduce muscle tone and respiratory effort is usually indicated. Patients must have an adequate peripheral IV line in place.

Emesis and subsequent aspiration are hazards encountered in emergency intubations. Before any airway manipulation, a source of suction and a supply of suction catheters should be readily available. The Sellick maneuver may help prevent aspiration. Downward

### BOX B-4 Complications of Intubation

- Hypoxemia and hypercarbia
- Aspiration of gastric content, oral content, or both
- Damage to teeth or gums
- Esophageal intubation
- Intubation of a mainstem bronchus

### BOX B-5 Equipment Required for Intubation

- Laryngoscope handle (checked to be in working order just before beginning intubation)
- Laryngoscope blades (sizes 00, 0, 1, 2, and 3)
- Suction source and suction catheters
- Endotracheal tubes (one size larger and one size smaller than those deemed appropriate by age)
- Oxygen supply
- Bag and mask for ventilation
- Tape and adhesive solution
- Expired carbon dioxide detector
- Nasogastric tube

pressure exerted on the cricoid cartilage effectively closes the esophagus and can prevent passive regurgitation and aspiration of oral or gastric material.

When possible, preoxygenation of the patient (3 minutes of breathing 100% oxygen) reduces hypoxemia and increases time for placement. Oxygen saturation, pulse rate, and blood pressure must be monitored during the attempt.

Sedation with a fast-acting agent must be given before neuromuscular blockade. Agents for this purpose include fentanyl, etomidate, and midazolam. Fentanyl is preferred if the patient exhibits evidence of hemodynamic instability, but may not provide anxiolysis or amnesia. Etomidate may precipitate an adrenal crisis and should be used by caregivers with experience in management of complications of intubation and sedation.

Vecuronium (0.1 mg/kg), rocuronium (0.3 mg/kg), and succinylcholine (1 to 2 mg/kg) all have the advantage of onset within 60 seconds. Succinylcholine has the added advantage of being rapidly metabolized, but its use is contraindicated in patients with hyperkalemia, burn injuries, and neuromuscular disease.

### TECHNIQUE OF INTUBATION

The equipment required for intubation is listed in Box B-5. Guidelines for laryngoscopy blade type and size, endotracheal tube size, depth of placement, and suction catheter diameter are provided in Table A-4, found in Appendix A, Pediatric Cardiopulmonary Resuscitation.

Perhaps the most important key to success of intubation is positioning the patient. The patient should be placed on a firm surface with the head extended. The neck is extended only slightly and the jaw pulled forward only slightly. To visualize the glottic opening correctly, and to prevent undue manipulation of the head and neck, the oral, pharyngeal, and tracheal axes must be in correct alignment.

The nose and mouth should be carefully suctioned. When possible, the child should be preoxygenated with 100% oxygen for 3 minutes. Care must be taken to prevent damage to teeth, gums, and lip with the blade. Loose deciduous teeth should be removed.

**Figure B-14** Laryngoscopy. Laryngeal structures in sagittal section (A), and as seen with the laryngoscope (B and C).

Figure B-14 illustrates the relationship of the laryngoscope blade to the epiglottis and vocal cords. After the equipment has been checked, the laryngoscope is held in the left hand. Appropriate medications are provided, and the laryngoscope blade is introduced into the mouth to the right of the tongue so that the tongue will be deflected to the left. The tip of the blade is inserted to the vallecula. The handle of the laryngoscope is tilted slightly backward and upward toward the operator. Care must be taken to avoid using the teeth or the alveolar ridge as a fulcrum. The vocal cords should be in full view. The endotracheal tube can be advanced along the right side of the child's mouth, inserted between the cords into the trachea, and advanced further to a position below the level of the vocal cords. The endotracheal tube should be positioned midway between the vocal cords and the carina. A carbon dioxide detection device and chest radiograph should be used to ensure appropriate placement. The size of the endotracheal tube, position of the tip of the tube in the trachea, and distance of insertion from the child's lip must be documented in the patient record.

### Confirmation of Placement of the Endotracheal Tube

Placement of the tube must be confirmed and documented. No single method is completely reliable. Box B-6 includes elements useful in confirmation of placement.

In a child with a perfusing rhythm, expired carbon dioxide is the most reliable method for verification of tube placement in the trachea. After 6 rescue breaths, the presence of yellow color change confirms placement

### BOX B-6 Confirmation of Correct Placement of Endotracheal Tube

- Symmetric chest rise
- Auscultation of air entry
- Water vapor in the tube
- Presence of exhaled carbon dioxide (in a child with a perfusing rhythm)
- Chest radiograph
- Direct laryngoscopy

### BOX B-7 Troubleshooting Patient Instability After Intubation

- Endotracheal tube too small
- Inadequate tidal volume
- Inadequate positive end-expiratory pressure
- Leak in the bag tube connections
- Pop-off valve leak
- Follow the DOPE mnemonic: **d**isplacement of endotracheal tube, **o**bstruction of endotracheal tube, **p**neumothorax, **e**quipment failure.

in the trachea. Exhaled carbon dioxide detection is not reliable in cardiac arrest. In patients with cardiac arrest, a positive color change predicts accurate placement. However, when pulmonary blood flow is absent, the absence of color change does not confirm esophageal misplacement. In a patient with cardiac arrest, placement should be confirmed by direct laryngoscopy and radiograph.

Caregivers should be mindful of conditions in which a false-negative result can occur. In some situations, an expired capnometer may produce false-negative results. In patients with severe asthma and pulmonary edema, the color change may be impaired. In patients who have received endotracheal epinephrine or who have aspirated gastric contents, the results are suspect. Again, in these situations, direct laryngoscopy is the best practice to confirm tracheal placement.

A slight air leak is to be expected with a tube of appropriate size. Small-cuffed endotracheal tubes are available and may be safely used in children who require high airway pressures during mechanical ventilation. An audible leak should be detected with bag insufflation at a pressure of 20 cm H<sub>2</sub>O.

If there is difficulty with adequate ventilation after intubation, a systematic approach will help identify the cause and solution (Box B-7).

### Postintubation Care

The intubated infant or child requires exacting nursing care. The patient needs monitoring of vital signs and frequent physical examinations to ascertain the

### BOX B-8 Safe Method for Suctioning

- The endotracheal tube is disconnected from the ventilator
- Normal saline (0.25–0.5 mL) is instilled into the tube
- The child receives ventilation for 60 seconds
- The head is turned to one side
- A sterile, end-hole catheter is passed a premeasured 1–2 cm beyond the distal orifice of the tracheal tube
- Suction is applied after the catheter has been pulled back 1 cm
- Suction is applied as the catheter is withdrawn over a 5-second interval
- The endotracheal tube is reconnected to the ventilator
- The head is turned to the opposite side and the procedure is repeated

adequacy of ventilation. Pneumothorax, tube obstruction, and dislodgement of the tube must be anticipated in the care of these children. Adequate sedation is mandatory.

Head and neck position alters the position of the tip of the endotracheal tube. In general, the tip of the tube follows the position of the chin. This factor should be borne in mind when radiographs are used to document the tube position in the trachea.

Suctioning the airway reduces tidal volume and available oxygen; it also predisposes the child to apnea and bradycardia. The physician and nurse should jointly decide how often suctioning should be performed; once an hour is a reasonable initial schedule. Box B-8 provides a safe method for suctioning.

## CIRCUMCISION

### Contraindications

The neonate should first be screened for any potential contraindications including coagulation, urologic, or general medical disorders.

### Coagulopathies

First, if any concerns exist, a pediatric hematologist should be consulted before proceeding with the circumcision. When obtaining consent from the parents, the examiner should ask about any history of bleeding disorders. If the family knows the specific diagnosis, the examiner should screen for that with the appropriate test (ie, factor VIII for hemophilia A, factor IX for hemophilia B, etc). If a family history of easy bruising or excessive bleeding with surgical procedures or trauma exists, screening coagulation tests should be conducted before proceeding. These tests include a complete blood count and platelet count, partial thromboplastin time (PTT), prothrombin time (PT), and thrombin time (TT). If any abnormalities are found, the circumcision should be deferred and a pediatric hematologist should be consulted to assist with diagnosis and further management. A family history of anemia is not a contraindication to circumcision.

### ***Urologic and Structural Contraindications***

**AMBIGUOUS GENITALIA.** In the presence of ambiguous genitalia, including phallus abnormalities or bilateral absent testicles, the circumcision should be deferred to urology and the sex of the baby confirmed by karyotype. The child should be evaluated for any possible virilizing syndrome, such as congenital adrenal hyperplasia.

**URINARY OBSTRUCTION.** The child should urinate before the circumcision is performed. If doubt exists as to the presence of urinary obstruction, circumcision should be deferred, and a pediatric urologist should be consulted.

**INADEQUATE SIZE AND MICROPENIS.** The penis should be at least 2 cm in length and of an adequate width to accommodate the smallest equipment available for the procedure.

**BURIED PENIS AND INCONSPICUOUS PENIS.** If an illusion of excessive foreskin is observed caused by the penis being covered by the surrounding suprapubic fat pad, the circumcision should be deferred until a later date when the penis is more exposed. If adequate exposure of the penis is not possible, too much foreskin may be removed, causing adhesions between the phallus and the surrounding skin during the healing process.

**EPISPADIAS, HYPOSPADIAS, AND MEGAMEATUS.** In these situations, the circumcision should be deferred and the patient referred to pediatric urology for cosmetic repair.

**SCROTAL WEBBING AND CHORDAE.** If webbing exists between the ventral phallus and scrotum, the circumcision should be deferred and the patient referred to pediatric urology for cosmetic repair, because this procedure may affect the ability for adequate erections in the future.

**PENILE TORSION.** The ventral raphae, which begins in the scrotum and proceeds onto the phallus, contains a vascular bundle that would make a circumcision more technically difficult because of increased risk of bleeding if more than a 90-degree rotation exists. For this reason and the possible need for cosmetic repair in the future, these patients should be referred to a pediatric urologist.

### ***Other Contraindications***

Relative contraindications would include respiratory distress, difficulty breathing, difficulty feeding, congestive heart failure, renal failure, and fever.

### ***Rate of Complications***

Complications that include bleeding, infection, accidental injury to the penis or surrounding structures, and an undesired cosmetic result occur in 1% of newborns receiving circumcisions. The risk of excessive bleeding occurs in 1 in 1,000 cases despite appropriate screening for bleeding disorders.

### ***Circumcision Procedures***

There are 3 options available for the circumcision procedure, with no studies showing any as superior to the others—the Gomco clamp, the Mogen clamp, and the PlastiBell.

### **BOX B-9 Sterile Equipment**

- 1% lidocaine without epinephrine
- Betadine swabs
- Sterile gloves
- 3 straight hemostats
- 1 narrow blunt probe
- 1 ten-blade scalpel
- 1 pair of scissors
- 4 × 4 gauze

Besides the specific equipment associated with each approach, other sterile equipment listed in Box B-9 should be available.

Procedural analgesia should be provided. The child should first be restrained with his legs immobilized and local anesthesia administered. A penile block should be performed by injecting 0.4 cc of 1% lidocaine without epinephrine targeting the dorsal penile nerves at base of the penis. The injection should be made at the dorsal aspect of the penis, parallel and just to the right and left of the phallus. An alternate block is circumferential, injecting 0.2 to 0.4 mL of 1% lidocaine without epinephrine each time to raise 3 to 4 wheals around the circumference of the penis. Additional analgesia can be offered using a pacifier dipped in a sucrose solution.

The penis should then be prepped and draped in a sterile fashion before proceeding with one of the 3 circumcision approaches.

### ***Gomco Clamp***

Three sizes of Gomco clamp bells are available, increasing based on the diameter of the glans (1.1, 1.3, and 1.6). All 3 sizes should be on hand in case a different size is found to be needed during the procedure. Each clamp should be checked, especially the seal, to maximize the possibility of obtaining hemostasis.

1. Using 2 hemostats, free up the end of the foreskin from the glans (Figure B-15, A), clamp the foreskin at the left lateral and right lateral edges, and stretch it, being cautious to clamp only the foreskin and not the glans.
2. Insert the third hemostat, running it under the foreskin to prevent accidentally inserting it into the urethra. Perform a gross blunt dissection around the glans to separate it from the synechia by opening the hemostat, avoiding the ventral frenulum because of the vascular structures it contains.
3. Repeat this process with the narrow probe, breaking down any adhesions.
4. Apply a hemostat to the dorsal foreskin, taking care to avoid going past the distal end of the glans. Close the hemostat for 5 seconds to obtain hemostasis.
5. Using scissors, make a dorsal slit through this crushed area with the scissors angled up to avoid cutting the glans.

**Figure B-15** The Gomco clamp method.

6. Retract the foreskin past the glans.
7. Run the narrow probe along the corona to break any adhesions that exist between the corona and the foreskin. Again, use caution around the frenulum, because this is the most common area of bleeding.
8. Reduce the foreskin.
9. Put the bell over the glans (Figure B-15, B), choosing a size that is able to get past the slit cut in the foreskin and covering the glans while not going beyond it. Err on the smaller size when choosing the bell to decrease the risk of removing excessive foreskin.
10. Clamp the 2 foreskin flaps together with a hemostat to make sure they are symmetric. Remove the 2 hemostats that were previously attached to each flap (Figure B-15, C).
11. Assemble the base of the Gomco clamp.
12. Use another hemostat to reach through the other side of the hole of the Gomco base, and secure both flaps of the foreskin at the site of the first hemostat.
13. Remove the bottom hemostat to allow the bell to be pulled through the hole in the base.
14. Pull the foreskin up with 1 hemostat to make it symmetric on top of the bell. Be sure that a symmetric amount of skin and the complete dorsal slit is through the other side of the Gomco clamp. Looking from the side of the Gomco clamp apparatus, make sure that there is no tension on the scrotum, which would suggest that too much foreskin is being removed, or that wrinkling is excessive, which would suggest that not enough foreskin is being removed (Figure B-15, D).
15. Tighten the clamp with the thumb stabilizing the top of the unit, the first finger on the shaft, and the third finger on top of the clamp. Do not torse the penis. Begin a timer to keep the clamp on for a total of 5 minutes to maximize hemostasis.
16. Incise the foreskin around the bell and discard it appropriately (Figure B-15, E). Scrape any remaining particles of foreskin to prevent the formation of inclusion cysts.
17. After 5 minutes, remove the clamp. Apply downward pressure on the foreskin and rock the bell away, breaking the skin-mucosal seal.
18. Dress the patient with lubricating jelly and cloth diaper within a disposable diaper to provide a pressure dressing, which is kept on for 2 hours. During that time, wound checks are performed regularly to check for bleeding. Acetaminophen should be offered for pain relief.

19. Bleeding is the most common complication. Any bleeding that might occur is usually controlled by direct pressure or with topical thrombin or epinephrine-soaked gauze. Very rarely, a suture may be needed for intractable bleeding.

### Mogen Clamp

1. Using 2 hemostats, free up the end of the foreskin from the glans, clamp the foreskin at the left lateral and right lateral edges, and stretch it, being cautious to clamp only the foreskin and not the glans.
2. Insert the third hemostat, running it under the foreskin to avoid accidentally inserting it into the urethra. Perform a gross blunt dissection around the glans to separate it from the synechia by opening the hemostat, avoiding the ventral frenulum because of the vascular structures it contains.
3. Repeat this process with the narrow probe, breaking down any adhesions.
4. Using a hemostat, elevate the foreskin in an upward and outward direction, which will retract the glans toward the scrotum, decreasing the risk of accidental injury.
5. Position the Mogen clamp around the foreskin with the grooved surface facing the glans and lift upwards (Figure B-16)
6. Close the clamp and keep it closed for 5 minutes to ensure hemostasis.
7. While the clamp is closed, using a scalpel, incise the foreskin distal to the clamp (Figure B-17).
8. After 5 minutes, remove the clamp.
9. Dress the patient with lubricating jelly and cloth diaper within a disposable diaper to provide a pressure dressing, which is kept on for 5 hours. During that time, wound checks are performed regularly to check for bleeding. Acetaminophen should be offered for pain relief.
10. Bleeding is the most common complication. Any bleeding that may occur is usually controlled by direct pressure or with topical thrombin or epinephrine-soaked gauze. Very rarely, a suture may be needed for intractable bleeding.

### PlastiBell

1. Using 2 hemostats, free up the end of the foreskin from the glans (see Figure B-18), clamp the foreskin at the left lateral and right lateral edges and stretch it, being cautious to clamp only the foreskin and not the glans.
2. Insert the third hemostat, running it under the foreskin to avoid accidentally inserting it into the urethra. Perform a gross blunt dissection around the glans to separate it from the synechia by opening the hemostat, avoiding the ventral frenulum because of the vascular structures it contains.
3. Repeat this process with the narrow probe, breaking down any adhesions.
4. Apply a hemostat to the dorsal foreskin, taking care to avoid going past the distal end of the glans. Close the hemostat for 5 seconds to obtain hemostasis.
5. Using a scissors, make a dorsal slit through this crushed area with the scissors angled up to prevent cutting the glans.
6. Retract the foreskin past the glans.
7. Run the narrow probe along the corona to break any adhesions that exist between the corona and the foreskin. Again, use caution around the frenulum because this is the most common area of bleeding.
8. A PlastiBell of appropriate size is placed around the glans, and the foreskin is reduced over it (Figure B-18).
9. A ligature is placed in the ridge of the bell and tightened as much as possible around the foreskin.
10. After keeping the ligature in place for 2 minutes to allow for hemostasis, the foreskin is sliced off distal to the PlastiBell using a scalpel.
11. The handle of the bell is then removed.

**Figure B-16** Positioning the Mogen clamp. Position the Mogen clamp around the foreskin with the grooved surface facing the glans and lift upwards.

**Figure B-17** Incising with the Mogen clamp. While the clamp is closed, using a scalpel, incise the foreskin distal to the clamp.

### The PlastiBell® Circumcision Method

1. An incision is made on the top of the foreskin after separating the foreskin from the glans. To minimize bleeding, the foreskin is previously crushed with a hemostat among the line of the incision for one minute.

2. A PlastiBell of the appropriate size is placed over the glans and the foreskin is pulled over the PlastiBell.

3. A ligature is tied around the foreskin over the tying groove in the PlastiBell. Foreskin beyond the ligature is trimmed away. The handle of the bell is snapped off, leaving the bell in place. The bell falls off 5–10 days later.

**Figure B-18** The PlastiBell method. (*Plastibell is a Registered Trademark of Briggs Medical Service Company. Reprinted with permission.*)

12. The remaining foreskin will become necrotic and separate with the PlastiBell in 5 to 10 days. Occasionally, edema will trap the bell on the shaft of the penis and the bell will need to be removed with a guide and ring cutter.

### Care of the Circumcision After the Procedure

After the procedure, parents should be advised that the glans of the penis will look swollen and bright red in color. Within 1 to 2 days, they will see a decrease in the swelling and a yellow covering over the glans, which is a part of the normal healing process.

After the initial 2-hour period using the cloth diaper (for the Gomco and Mogen clamp procedures), standard diapers may be used. The parents should be advised to use approximately 1 teaspoon of petroleum jelly on the front of the diaper with every diaper change until the coloration of the penis returns to normal, which can take between 4 and 14 days. For the first 2 to 3 days, the entire penis can be cleaned by pouring warm water over it. Afterward, if necessary, mild soap may be used.

Infant acetaminophen can be used as directed for pain relief.

### When to Contact a Physician

- Signs of infection are observed, including fever, increased swelling and redness of the penis, and greenish-yellow discharge.
- Active bleeding occurs from the penis. (Observing some blood spots on the baby's diaper for the first 1 to 2 days is normal.)
- The baby does not urinate once within 24 hours after the circumcision.
- Signs of paraphimosis are observed, including edema, tenderness, and erythema of the glans or foreskin.

## Appendix C

FORMULAS AND REFERENCE  
RANGE VALUES

Lamia Soghier, MD

## CONVERSION FORMULAS

## HEIGHT (LENGTH)

1 mm = 0.04 in	1 in = 2.54 cm
1 cm = 0.4 in	1 m = 39.37 in

## WEIGHT

60 mg = 1 g	1 L = 1.06 qt
28.35 g = 1 oz	1 fl oz = 29.57 mL
453.6 g = 1 lb	1 tbsp = 15 mL
1,000 g = 1 kg	1 tsp = 5 mL
1 kg = 2.2046 lb	

## MILLIGRAM–MILLIEQUIVALENT CONVERSIONS

$\text{mEq/L} = \text{mg/L} \times \text{valence/atomic weight}$   
 $\text{Equivalent weight} = \text{atomic weight/valence}$   
 $\text{mg/L} = \text{mEq/L} \times \text{atomic weight/valence}$

## MILLIGRAM–MILLIMOLE CONVERSIONS

$\text{mmol/L} = \text{mg/L} \div \text{molecular weight}$

## MILLIOSMOLS

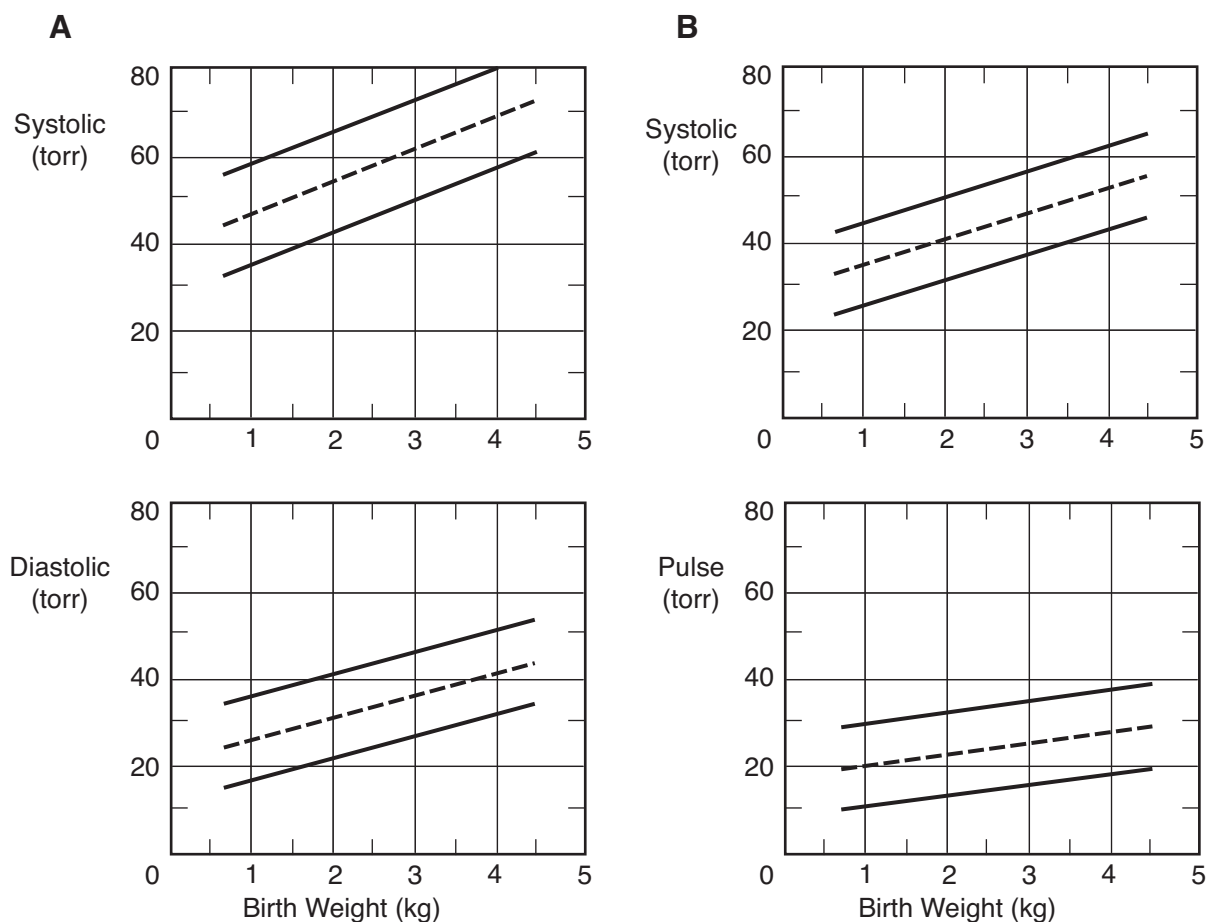

The milliequivalent (mEq) is roughly equivalent to the milliosmol (mOsm), the unit of measure of osmotic pressure or tonicity. One osmole (Osm) is the amount of a substance that dissociates in solution to form one mole (mol) of osmotically active particles.

## HEART RATE

## Average Heart Rate for Infants and Children at Rest

AGE	HEART RATE AT REST (BEATS/MIN)
Birth–1 mo	100–180
1–12 mo	100–180
1–3 y	70–110
4–6 y	70–110
7–12 y	70–110
13–19 y	55–90

BP, blood pressure.

Note: The 90th percentile is 1.28 SD, the 95th percentile is 1.645 SD, and the 99th percentile is 2.326 SD over the mean.

## DETERMINING BODY SURFACE AREA

Based on the nomogram, a straight line joining the patient's height and weight will intersect the center column at the calculated body surface area (BSA). For children of normal height and weight, the child's weight in pounds is used, then the examiner reads across to the corresponding BSA in meters squared. Alternatively, Mosteller's formula can be used.

Alternative (Mosteller's formula)

$$\text{Surface area (m}^2\text{)} = \sqrt{\frac{\text{Height (cm)} \times \text{Weight (kg)}}{3600}}$$

Nomogram and equation to determine body surface area.

## BONE AGE

### Sontag Method

The Sontag method is used to evaluate the skeletal development of children between 1 and 60 months of age:

1. Radiographs are taken of all epiphyseal centers on the left side of the body: shoulder, elbow, wrist and hand, hip, knee (anteroposterior [AP] views before 24 months of age, lateral views after 24 months), and ankle and foot (AP views before 48 months of age, lateral views after 48 months).
2. All ossification centers in the left half of the body are counted. A center is counted as soon as it casts any shadow on the roentgenogram.
3. The number of ossification centers is compared with normal values for the patient's age. (For normal values, see Sontag and colleagues' article "Rate of Appearance of Ossification Centers From Birth to the Age of Five Years" in the November 1939 issue of *American Journal of Diseases of Children*.)

### Gruelich and Pyle Method

The Gruelich and Pyle method is used to evaluate the skeletal development of girls 5 to 18 years old and of boys 5 to 19 years old:

1. A radiograph is taken of the left hand and wrist.
2. Calculation of the skeletal development is based on the order of appearance and maturation of the epiphyseal centers. (For normal values, see Gruelich and Pyle's *Radiographic Atlas of Skeletal Development of the Hand and Wrist*, 2nd ed. [Stanford University Press, Stanford, CA].)

CSF, Cerebral spinal fluid; SD, standard deviation.

Calculating the ratio of red blood cells (RBCs) to white blood cells (WBCs) in CSF

General rule: For every 500 RBCs in CSF, it is acceptable to have 1 WBC.

Normal ratio of RBCs to WBCs in peripheral blood is 1,000 RBCs: 1–2 WBCs × 10<sup>6</sup>/L.

$$\text{Number of WBCs introduced into the CSF per L} = \frac{(\text{WBC}_{[\text{peripheral}]} \times \text{RBC}_{[\text{CSF}]})}{\text{RBC}_{(\text{peripheral})}} \times 10^6/\text{L}$$

Compare this number with the actual number of WBCs in the CSF.

1,000 × 10<sup>6</sup>/L RBCs in CSF raises CSF protein by approximately 0.015 g/L.

Note: correction factors should not be used to reassure that meningitis is unlikely.

Note: Values are presented as medians (10th and 90th percentiles). Subset counts (numbers of cells per microliter  $\times 10^{-3}$ ) were obtained by multiplying subset percentages times anchor marker percentages (ie, CD3CD4 or CD3CD8) of total CD45 lymphocyte population times the absolute lymphocyte count (white blood cells  $\times$  lymphocyte percentage).  
 From Shearer WT, Rosenblatt HM, Gelman RS, et al; Pediatric AIDS Clinical Trials Group. Lymphocyte subsets in healthy children from birth through 18 years of age: the Pediatric AIDS Clinical Trials Group P1009 study. *J Allergy Clin Immunol*. 2003;112(5):973-980. ## Neutrophil Count Reference Ranges for Term Neonates

**A**, Solid lines represent the upper and lower boundaries of total neutrophil count for this full-term population. Dots represent individual data, and numbers represent number of values at the same point. **B** and **C**, Immature neutrophil count and I:T proportion: reference range in the first 60 hours of life for term neonates. (Reprinted from Manroe BL, Weinberg AG, Rosenfeld CR, et al. *The neonatal blood count in health and disease. I. Reference values for neutrophilic cells.* J Pediatr. 1979;95[1]:89, with permission from Elsevier.)

**Thyroid Function Tests****Reference Ranges in Very Low-Birth-Weight Infants**

SCREENING T4 LEVELS BY BIRTH WEIGHT AND POSTNATAL AGE (mcg/dL)			
POSTNATAL DAYS	VLBW ( $<1,500$ g)	LBW ( $<2,500$ g)	TERM
1–3	$7.9 \pm 3.3$	$11.4 \pm 2.5$	$12 \pm 1.9$
4–6	$6.5 \pm 2.9$	$9.9 \pm 2.5$	$11 \pm 2.5$
7–10	$6.3 \pm 3.0$	$9.5 \pm 2.3$	
11–14	$5.7 \pm 2.8$	$9.2 \pm 2.1$	
15–18	$7.0 \pm 2.5$	$9.1 \pm 2.3$	
29–56	$7.8 \pm 2.5$	$9.3 \pm 3.3$	

LBW, low birth weight; T4, thyroxine; VLBW, very low birth weight. Data expressed as  $\pm$  SD.

From Frank JE, Faix JE, Hermos RJ, et al. Thyroid function in very low birth weight infants: effects on neonatal hypothyroidism screening. *J Pediatr*. 1996;128(4):548. Reproduced with permission. Copyright © 1996 Elsevier.

Plasminogen (CTA, U/mL)	1.95 ± 0.35 (44)	2.17 ± 0.38 (60)	1.98 ± 0.36 (52)	2.48 ± 0.37 (44)	3.01 ± 0.40 (47)	3.36 ± 0.44 (29)

Note: All factors except fibrinogen and plasminogen are expressed as units per milliliter, where pooled plasma contains 1.0 U/mL. Plasminogen units are those recommended by the Committee on Thrombolytic Agents (CTA). All values are expressed as mean ± 1 SD.

aPTT, activated partial thromboplastin time; HMWK, high molecular-weight kininogen; PK, prekallikrein; PT, prothrombin time; TCT, thrombin clotting time; vWF, von Willebrand factor.

<sup>a</sup>Values that do not differ statistically from the adult values.

<sup>b</sup>These measurements are skewed because of a disproportionate number of high values. The lower limit that excludes the lower 2.5th percentile of the population has been given in the respective figures. The lower limit for factor VIII was 0.50 U/mL at all time points for the infant.

## FORMULAS

### Preparation of Infant Formulas for Standard and Soy Formulas

FORMULA TYPE	CALORIC CONCENTRATION (kcal/oz)	AMOUNT OF FORMULA	WATER (oz)
Liquid concentrates (40 kcal/oz)	20	13 oz	13
	24	13 oz	8.5
	27	13 oz	6.3
	30	13 oz	4.3
Powder (44 kcal/scoop)	20	1 scoop	2
	24	3 scoops	5
	27	3 scoops	4.25
	30	3 scoops	4

<sup>a</sup>Does not apply to Enfamcare, Neocate Infant, Neosure; Enfamil AR should not be concentrated greater than 24 kcal/oz. Use a packed measure for Nutramigen LIPIL and Pregestimil LIPIL and unpacked powder for all others.  
Adapted from Koldobskiy M, Thompson J. Nutrition and growth. In: Engorn B, Flerlage J, eds. *The Harriet Lane Handbook*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2015:485–522. Reproduced with permission. Copyright © 2015 Elsevier.

### Common Caloric Supplements<sup>a</sup>

COMPONENT	CALORIES
Protein	Beneprotein (powder)
	ProSource Protein Powder
	Complete Amino Acid Mix
	Liquid Protein Fortifier
Carbohydrate	Polycose
	SolCarb
Fat	MCT oil <sup>b</sup>
	Vegetable oil
	Microlipid
	Liquigen (emulsified MCT)
Fat and Carbohydrate	Duocal

MCT, medium-chain triglyceride.

<sup>a</sup>Use these caloric supplements when you want to increase protein or when you have reached the maximum concentration tolerated and wish to further increase caloric density.

<sup>b</sup>MCT oil is unnecessary unless there is fat malabsorption.

Adapted from Koldobskiy M, Thompson J. Nutrition and growth. In: Engorn B, Flerlage J, eds. *The Harriet Lane Handbook*. 20th ed. Philadelphia, PA: Elsevier Saunders; 2015:485–522. Reproduced with permission. Copyright © 2015 Elsevier.

## The landmark guide to pediatric medicine— updated and streamlined for today's clinicians and students

For more than 80 years, the American Academy of Pediatrics (AAP) has been the nation's leading and most trusted child health authority. The new second edition of the *AAP Textbook of Pediatric Care* continues the tradition by providing a wealth of expert guidance spanning every aspect of current clinical practice.

**COMPREHENSIVE SCOPE** More than 3,000 pages cover screening, pathophysiology, diagnosis, treatment, management, prevention, critical care, practice management, ethical and legal considerations, and much more.

**ESSENTIAL CLINICAL GUIDANCE** Step-by-step recommendations on diagnosis, evaluation, treatment, when to admit, and when to refer.

**PRACTICAL FOCUS** Directly addresses day-to-day practice concerns for efficient patient problem-solving.

**EVIDENCE-BASED APPROACH** State-of-the-art approach includes relevant AAP policy, plus links to essential online tools for practice.

### New and revised in the second edition

- 75 new chapters (**375 total chapters**) covering the full breadth of pediatric practice
- Extensive coverage of presenting signs and symptoms
- New sections on pediatric assessment and care of special populations
- Comprehensive coverage of health supervision
- Enhanced focus on patient- and family-centered medical home, plus expanded coverage of mental health topics
- eBook accessible on mobile devices

*AAP Textbook of Pediatric Care*, 2nd Edition, and related products can be purchased directly from the AAP at [shop.aap.org](http://shop.aap.org).
